Abstract

We consider control problems in many-server queueing networks, with impatient customers. In particular, we focus on models with two customer classes and one, or two, service stations. Each customer can receive service only once, possibly in either of the available stations; and can also abandon while waiting in queue. The service is assumed exponential with rates depending on station type only.

Our objective is to find a policy minimizing the expected discounted linear holding cost of customers in the queue. The problem is considered in the so-called Quality and Efficiency-Driven regime, when both the arrival rates and the number of servers are large, and the system is critically loaded. We use Markov Decision Processes techniques to investigate properties of an optimal policy, as well as to plot the approximated optimal cost function for sets of given parameters. Our conclusions are: (a) an optimal policy depends on the total number of customers in system only; (b) it is optimal to keep idleness in the station with lower service rate; (c) an optimal policy is “bang-bang”, dictating to rearrange the customers in such a way that, at any given moment of time, only one type of customers is waiting (and the customers of the other type are all being served). The decision, we argue, depends on whether the derivative of the optimal cost function is greater than the ratio $\frac{c_1-c_2}{\theta_1-\theta_2}$; with $c_i$ and $\theta_i$ being, respectively, the holding cost rate and the abandonment rate of class $i$.

The second part of the thesis introduces a simple algorithm for simulating G/G/N queueing system, which is then extended to more complex networks.
I would like to express my deepest gratitude to my supervisor, Dr. Gennady Shaikhet, for all the guidance, support, patience and encouragement he provided throughout my graduate study. I greatly appreciate the freedom he gave me to choose my thesis topic, which made my research experience a truly enjoyable journey. I am deeply thankful for his devoted time and effort in making this thesis possible. I am particularly grateful for his generous financial help that saw me through to the end.

I wish to express special thanks to Dr. Matthew Kennedy for his understanding and encouragement during a very difficult time of my thesis work. I especially value our friendship.

I must thank all the lovely people I met in the Graduate Student Lab for their kindness and warm friendships. Their company made my study life less lonely, more colorful, and more memorable.

Finally, I wish to thank my family. Thanks to my parents for their love, devotion, unconditional support and unwavering confidence in me. Thanks to my husband for his love, patience, tolerance, unfailing help, continuous encouragement and always being there for me.

\( S \) State space.

\( (x_1, x_2) \) A state described by the numbers of customers in class 1 and 2.

\( A(x_1, x_2) \) Set of actions available at state \((x_1, x_2)\).

\( f \) A stationary policy.

\( f^* \) Optimal policy for certain performance criterion.

\( F \) Set of all stationary policies.

\( \alpha \) The discount factor.

\( V_\alpha(x_1, x_2, f) \) Expected discount cost under policy \( f \) given initial state \((x_1, x_2)\).

\( V^*_\alpha(x_1, x_2) = \min_{f \in F} V_\alpha(x_1, x_2, f) \), the optimal discount cost.
Chapter 1

Introduction

Since introduced by Erlang in 1920s the queueing theory has become a fundamental research area with a wide range of practical applications. Various queueing models have been developed for analyzing real-life problems. Such models are generally classified into two types: descriptive and prescriptive [1]. Descriptive models are used to analyze actual situations, and play a dominant role in a standard queueing theory. Prescriptive models, in turn, prescribe the desired behavior, and are generally referred to as design and control of queues. They serve to prescribe optimal system parameters (such as optimal service rate, the optimal number of servers), as well as an optimal service discipline. Design models are generally static in nature; that is, cost or profit functions are superimposed and to be optimized with respect to parameters like arrival rate $\lambda$, service rate $\mu$, or the number of servers $N$ [1]. In contrast, control models are usually more dynamic in nature and focus on determining the optimal policy.

Unlike the passive development of design models, research in control models has been growing at an ever-increasing rate over the past decades. Control models have been applied to solve numerous problems in various fields, including call center systems [2], energy management systems [3], health care systems from kidney allocation [4] to emergency medical services [5], computers and communication systems [6], and manufacturing systems [7].

Certain issues have been discussed in the control of queueing models. Routing and scheduling control (RSC) problem is among the most interesting and challenging problems. The routing problem is to decide, upon a customer’s arrival, to which of the idle servers, if any, should the customer be routed. The scheduling problem is to determine, upon a service completion, which of waiting customers, if any, should
be scheduled to get service. Complex model structure often leads to various choices of routing and scheduling policy. Garnett and Mandelbaum [8] introduced some canonical queueing models, as shown in Figure 1.1.

![Figure 1.1: Some canonical queueing models](image)

For example, in a V model, a single pool of servers handles two (or more) classes of customers. In a N model, pool 1 serves customers of class 1, while pool 2 serves customers of both classes. In a X model, two classes of customers can be served by either of the two pools. All the models in Figure 1.1 can be enriched by allowing abandonment of waiting customers.

Besides model structure, aspects such as the number of servers, heavy traffic regime and cost function also contribute to the diversity of queueing control problem. For instance, Van Mieghem [9] and Mandelbaum and Stolyar [10] considered a queueing model with $I$ classes of customers and $J$ non-identical servers working in parallel with convex cost function in the conventional, single-server, heavy traffic regime. They obtained the generalized $c\mu$-rule ($Gc\mu$) as the asymptotically optimal scheduling policy. The policy can be described as follows: at each time $t$, when server $j$ becomes free, the next customer scheduled to it is a class-$i$ customer such that $i \in \arg\max_i C'_i(Q_i(t))\mu_{ij}$. Here $C'$ is the derivative of cost function $C$, $Q_i(t)$ is the queue length of class-$i$ customers at time $t$, and $\mu_{ij}$ is the average service rate of class-$i$ customers served by server $j$. 
An alternative to index control is threshold control. Bell and Williams [11] looked at a two-parallel-server system structured as a N model under linear holding cost. They considered a parameter regime in which the system is heavily loaded and allows complete resource pooling. A threshold policy is proved to be asymptotically optimal; that is, the priority of service is determined by whether or not the queue length has exceeded the threshold. The results were extended to general parallel server systems in [12].

In many-server queueing systems, the RSC problems turn out to be more difficult than in parallel single-server systems. An asymptotic approach, where a diffusion control problem is obtained in the heavy traffic limit through parametrization of the model, is often used to simplify the problem. The works of Harrison and Zeevi [13] and Atar, Mandelbaum and Reiman [14] analyzed V model in which a pool of statistically identical servers caters to multiple classes of impatient servers. Harrison and Zeevi [13] considered a Markovian model in the Quality- and Efficiency-driven (QED) regime and found the optimal scheduling showing an extremal or “bang-bang” character. Atar, Mandelbaum and Reiman [14] established a relation between their scheduling problem and a diffusion control problem in the QED regime. Then, by solving the diffusion control problem via Hamilton-Jacobi-Bellman (HJB) equation, they attained the asymptotically optimal policy for the original queueing system.

Tezcan and Dai [15] studied a many-server N model under some conditions on service, abandonment and cost parameters. To be specific, they assumed the service rates are pool-dependent and customers of the cheaper class are more likely to abandon the system. In QED regime, a $c\mu$-type static priority policy is proved asymptotically optimal for this queueing system. One needs only the holding cost and service rate to establish the policy.

For many-server models with $I$ customer classes and $J$ server pools, Gurvich and Whitt [16] proposed a control policy named Fixed-Queue-Ratio (FQR) rule. It indicates that, when a service ends, the next customer scheduled should be the longest-waiting one of the class which is eligible to be served and has the queue length most exceeding a specified proportion of the total queue length. This results in a dimension reduction; that is, the vector-valued queue-length process is asymptotically evolving as a one-dimensional process. Atar, Mandelbaum and Shaikhet [17] dealt with the similar queueing model in two special cases. First, when the service rates depend only
on the pool, the control problem is shown to be asymptotically reducible to a one-dimensional diffusion control problem. Secondly, they present certain simplifications for the case of the class-dependent service rates.

However, a very interesting case of many-server models with pool-dependent service rates has not been solved explicitly yet. We consider, for example, a two-class V model in which the holding cost rates \( c_1, c_2 \) and the abandonment rates \( \theta_1, \theta_2 \) satisfy

\[
  c_1 > c_2 \quad \text{and} \quad \theta_1 > \theta_2. \quad (1.1)
\]

This condition indicates that, in order to minimize the total linear holding cost, one must make a trade-off between low cost rate and high abandonment rate.

Shaikhet [18] suggested the optimal policy of this model is “bang-bang”. Based on the results of [17], this two-dimensional control problem can be reduced to a one-dimensional one in which the only control variable is the allocation of waiting population between the classes. Then, the corresponding one-dimensional HJB equation shows that the control variable can only take two extreme values. It implies that the optimal control might be a threshold policy.

In this thesis, we find the optimal control and provide a detailed proof by formulating the problem as a Markov Decision Process (MDP). The results confirm the conjecture in [18]; that is, the optimal scheduling is proved to be a threshold policy where the priority of customer class is decided based on the total number of customers in the system. By applying the same approach, we also solve the optimal control problems for pool-dependent N and X models, for which the cost and abandonment rates satisfy (1.1). The results are similar to those of the above V model.

The other part of the thesis presents an approach of discrete-event simulation. Simulation is an effective approach to analyze complex system. In queueing theory, simulation is often used to estimate the measures of performance of a queueing system in steady state. As a result, one can compare different control policies with the estimates. For example, Garnett and Mandelbaum [8] used simulation to demonstrate that various control policies end in dramatic differences in the performance of system. In [19], Armony and Ward provided simulation results to show that their threshold routing policy outperforms the routing policies commonly used in call centers such as faster-server-first (FSF) and longest-idle-server-first (LISF) policies. Similar usage of simulation can also be found in [20] and [21].

In order to describe the contents of the thesis, we introduce a shorthand notation
of queueing system. A/B/N denotes a N-server queueing system, where A and B indicate the interarrival time distribution and the service time distribution, respectively. Some standard symbols for A and B are M (exponential), D (deterministic) and G (general). The symbol G represents a general probability distribution; that is, no assumption is made about the precise form of the distribution. Thus, for example, G/M/2 means a two-server system with general distributed interarrival times and exponentially distributed service times.

It is well known that system M/M/N can be easily simulated by using the memoryless property of exponential distribution. Meanwhile, the algorithm of simulating G/G/1 has been provided by Ross [22]. However, simulation of the most general system G/G/N remains a challenging problem. In this thesis, we present a simple algorithm for G/G/N. The simulation approach can be applied to more complex queueing systems, for example, any of the models in Figure 1.1. We include three examples in the thesis: G/G/N with abandonment, V model and N model.
Chapter 2

Asymptotic Analysis and Control of Many-Server Queueing Systems

In this chapter, we will review the Quality and Efficiency Driven (QED) regime, which is characterized by both the arrival rates and the number of servers being very large, with the utilization close to 1. It will be shown that, under such a regime, the system fluctuates around the so-called static fluid model with fluctuations being of much smaller order than the arrival rates. We characterize the fluctuations in the case of single-class single-station network and then present the method of controlling fluctuations for more general network structures.

2.1 The QED regime for M/M/N queues

The QED regime was first formalized by Halfin and Whitt [23] for the M/M/N model. A striking feature of the regime is that, despite the critical load, the delay probability (i.e., the probability that an arriving customer would have to wait) does not converge to 1, but to some constant strictly less than 1. That is to say, the system achieves high levels of both server efficiency and service quality. In what follows we elaborate in more detail.

Consider a sequence of M/M/N systems indexed by \( n \to \infty \). Assume that the number of servers \( N = n \). Let \( \lambda^n \) and \( \mu^n \) be the arrival and the service rates, satisfying \( \frac{\lambda^n}{n} \to \mu \) and \( \mu^n \to \mu \) for some constant \( 0 < \mu < \infty \). Define the system utilization \( \rho^n = \frac{\lambda^n}{n\mu^n} \) and assume

\[
\sqrt{n}(1 - \rho^n) \to \beta, \quad \text{for some } \beta \in (0, \infty).
\]  (2.1)
Define the centered, normalized queue length as
\[
\hat{X}^n(t) = \frac{X^n(t) - n}{\sqrt{n}}, \quad t \in [0, \infty).
\] (2.2)

The following theorem states that, with such parameters, the system is almost full, fluctuating around the static average value of \(n\), with fluctuations being of the order \(O(\sqrt{n})\).

**Theorem 2.1.** (*Halfin and Whitt, 1981 [23]).

1. Assume \(\hat{X}^n(0) \Rightarrow \hat{X}(0)\). Then \(\hat{X}^n\) converges weakly to a diffusion process \(\hat{X}\) characterized by
\[
\hat{X}(t) = \hat{X}(0) + \int_0^t b(\hat{X}(s))ds + \sqrt{2\mu}W(t).
\]
Here \(W(t)\) is a standard Brownian motion, and the drift \(b\) is given as
\[
b(x) = \begin{cases} 
-\mu\beta & x \geq 0, \\
-\mu(x + \beta) & x < 0. 
\end{cases}
\]

2. The probability of delay has a nondegenerate limit as follows:
\[
\lim_{N \to \infty} P(X^N(\infty) \geq N) = \alpha, \quad 0 < \alpha < 1,
\] (2.3)
where \(\alpha\) is related to \(\beta\) from (2.1) via \(\alpha = [1 + \beta\Phi(\beta)/\phi(\beta)]^{-1}\). (Here \(\Phi\) and \(\phi\) are, respectively, the distribution and density functions of the standard normal distribution).

The results were later extended for M/M/N queues with abandonment by Garnett, Mandelbaum and Reiman [24]. Because of its desirable features, the QED regime has also been considered for multi-class many-server systems such as modern telephone call center (see [2] for a review).
2.2 The QED regime for multi-class many-server queueing systems

We study a Markovian queueing system with $I$ customer classes and $J$ server pools (see Figure 2.1 as an example). Let $\mathcal{I} = \{1, \ldots, I\}$ and $\mathcal{J} = \{I + 1, \ldots, I + J\}$ denote the index sets for customer classes and server pools, respectively.

Consider a sequence of the above systems indexed by $n \to \infty$. For $i \in \mathcal{I}$, customers of class $i$ arrive according to a Poisson process of rate $\lambda_i^n$, and their patience time is exponentially distributed with rate $\theta_i^n$. A server pool $j$, for each $j \in \mathcal{J}$, consists of $N_j^n$ statistically identical and independent servers, providing an exponential ($\mu_{ij}^n$) service to class-$i$ customers.

![Figure 2.1: A system with two customer classes and three server pools](image)

2.2.1 The fluid model

In the QED heavy traffic regime, the system is supposed to fluctuate around the so-called critically loaded static fluid model, which was proposed by Harrison and López [25]. For this reason, we assume that there exist constants $\{\lambda_i\}, \{\mu_{ij}\}, \{\nu_j\}, \{\theta_i\}$ so that the system’s parameters satisfy

\[
\lambda_i^n = n \lambda_i + O(\sqrt{n}), \quad i \in \mathcal{I},
\]

\[
n \mu_{ij}^n = n \mu_{ij} + O(\sqrt{n}), \quad i \in \mathcal{I}, \; j \in \mathcal{J},
\]

\[
n \theta_i^n = n \theta_i + O(\sqrt{n}), \quad i \in \mathcal{I},
\]
\[ N_j^n = n \nu_j + O(\sqrt{n}), \quad j \in \mathcal{J} \]  

These fluid level parameters \( \{\lambda_i\}, \{\mu_{ij}\}, \{\nu_j\} \) should guarantee that the system is critically loaded in a following sense: there exists a unique optimal solution \((\xi^*, \rho^*)\) to the below linear program, satisfying \( \sum_{i \in \mathcal{I}} \xi_{ij}^* = 1 \) for all \( j \in \mathcal{J} \) (and consequently \( \rho^* = 1 \)):

\[
\begin{align*}
\text{Minimize} \ & \rho \in \mathbb{R}_+ \ \text{subject to} \\
\quad & \sum_{j \in \mathcal{J}} \nu_j \mu_{ij} \xi_{ij} = \lambda_i, \\
\quad & \sum_{i \in \mathcal{I}} \xi_{ij} \leq \rho, \quad i \in \mathcal{I}, \ j \in \mathcal{J} \\
\quad & \xi_{ij} \geq 0.
\end{align*}
\]  

(2.8)

One gets a deterministic allocation matrix \( \xi^* \), where for \((i, j) \in \mathcal{I} \times \mathcal{J} \), the entry \( \xi_{ij}^* \) represents the fraction of pool-\( j \) work dedicated to class-\( i \) customers on the fluid level.

For example, consider a fluid system with parameters \( n = 100, \lambda_1 = 2, \lambda_2 = 1, \mu_{11} = 2, \mu_{12} = 2, \mu_{21} = 2, \mu_{22} = 1, \nu_1 = 1, \) and \( \nu_2 = 1 \). If we allocate the fluid as \( \xi_{11} = 1, \xi_{12} = 0, \xi_{21} = 0, \) and \( \xi_{22} = 1 \), the utilization of both pools are \( \sum_i \xi_{i1} = \sum_i \xi_{i2} = 100\% \). But the system is not critically loaded because 100\% is not the optimal \( \rho \). It can be shown that the utilization decreases to 75\% if we reallocate the fluid as \( \xi_{11} = 0.25, \xi_{12} = 0.75, \xi_{21} = 0.5, \) and \( \xi_{22} = 0 \).

\[ (a) \ (\xi_{11}, \xi_{12}, \xi_{21}, \xi_{22}) = (1, 0, 0, 1) \quad (b) \ (\xi_{11}, \xi_{12}, \xi_{21}, \xi_{22}) = (0.25, 0.75, 0.5, 0) \]

**Figure 2.2:** A non-critically loaded system
An example of critically loaded system is that $n = 100$, $\lambda_1 = 7.5$, $\lambda_2 = 2$, $\mu_{11} = 4$, $\mu_{12} = 7$, $\mu_{21} = 2$, $\mu_{22} = 4$, $\nu_1 = 1$, and $\nu_2 = 1$. In this case, $\xi_{11}^* = 1$, $\xi_{12}^* = 0.5$, $\xi_{21}^* = 0$, and $\xi_{22}^* = 0.5$ is the unique optimal allocation with $\rho^* = 1$.

![Diagram of a critically loaded system]

**Figure 2.3:** A critically loaded system

Throughout the thesis, we keep the notation $\xi_{ij}^*$. We also denote

$$a1\psi_{ij}^* = \xi_{ij}^* \nu_j, \quad x_i^* = \sum_{j \in J} \xi_{ij}^* \nu_j, \quad i \in I, \quad j \in J.$$  \hfill (2.9)

### 2.2.2 Important estimates

Our models of interest are the so-called $V$, $N$ and $X$ models that introduced in Figure 1.1. Let $X^n_i(t)$ denote the total number of class-\(i\) customers in the system at time $t$. Considering work-conservation (i.e. a server is allowed to be idle only when no customer that it can serve is waiting), it has been shown in Atar [26] that in $V$ and $N$ models, where the graph of the activities $(i,j)$ in the *static fluid model* is a tree, the quantities

$$\hat{X}^n_i(t) = \frac{X^n_i(t) - nx_i^*}{\sqrt{n}}, \quad i \in I$$  \hfill (2.10)

satisfy, for each $\gamma > 0$

$$\mathbb{P}(\|\hat{X}^n_i\|^* > n^\gamma) \to 0 \quad \text{as} \quad n \to \infty.$$  \hfill (2.11)

In other words, the system fluctuates around the static fluid model.
A model is called pool-dependent if the service rates depend only on the pool \((\mu_{ij}^n = \mu_{ij}^0)\). If a X model is in the pool-dependent case, a weaker version of (2.11) was provided in [17]:

\[
P(|\hat{X}_{it}| > n^\gamma) \to 0 \quad \text{as} \quad n \to \infty. \tag{2.12}
\]

Based on the above claims, we present some important estimates needed to establish Markov decision processes in Chapter 3.

**V model**

In a two-class V model, \(I = \{1, 2\}\) and \(J = \{1\}\). \(X^n_1(t)\) and \(X^n_2(t)\) fluctuate within the rectangle region

\[
\{(X^n_1(t), X^n_2(t)) \mid X^n_i(t) \in [nx^*_i - n^{\frac{1}{2} + \gamma}, nx^*_i + n^{\frac{1}{2} + \gamma}], \forall i \in I\}. \tag{2.13}
\]

In addition, \(N^n + O((N^n)^{\frac{7}{4}})\) is an upper bound of the total number of customers for the V model in the QED limit; that is,

\[
P(X^n_1(t) + X^n_2(t) \geq N^n + O((N^n)^{\frac{7}{4}})) \to 0 \quad n \to \infty, \tag{2.14}
\]

**N model**

In a N model, \(I = \{1, 2\}\) and \(J = \{1, 2\}\). Assume that pool 1 serves customers of class 1 and pool 2 serves customers of both classes. Same as above, \(X^n_1(t)\) and \(X^n_2(t)\) fluctuate within the rectangle region

\[
\{(X^n_1(t), X^n_2(t)) \mid X^n_i(t) \in [nx^*_i - n^{\frac{1}{2} + \gamma}, nx^*_i + n^{\frac{1}{2} + \gamma}], \forall i \in I\}; \tag{2.15}
\]

The asymptotically upper bounds of the number of customers in class 1 and class 2 are as below.

\[
P(X^n_1(t) \geq N^n_1 + N^n_2) \to 0 \quad n \to \infty; \tag{2.16}
\]

\[
P(X^n_2(t) \geq N^n_2) \to 0 \quad n \to \infty; \tag{2.17}
\]
X model

In a X model, \( \mathcal{I} = \{1, 2\} \) and \( \mathcal{J} = \{1, 2\} \). Customers of both classes can be served by either of the two pools. According to (2.12),

\[
P(X_1^n(t) + X_2^n(t) \geq N_1^n + N_2^n + O((N_1^n + N_2^n)^{3/2})) \to 0 \quad n \to \infty. \tag{2.18}
\]

Hence, \( N_1^n + N_2^n + O((N_1^n + N_2^n)^{3/2}) \) is an upper bound of the total number of customers in the QED limit.

2.3 Control of multi-class many-server queues

The following section introduces the asymptotic way of solving control problems for many-server queues in the QED regime. It shows that, when scaled and centered around static fluid level (2.8), the queue process will asymptotically behave like a controlled diffusion with a drift control, which also partially explains the intuition behind the estimate (2.11). Given a cost, one obtains a diffusion control problem that can sometimes be solved explicitly and suggests a so-called asymptotically optimal solution to the original problem. In our case, however, a solution is not readily available, hence we present the MDP solution in Chapter 3. Nevertheless, very useful insights can be derived from the diffusion representation. Namely, the nature of the controls is to regulate the distribution of queues and idleness among the classes and stations; besides, an important dimension reduction, sometimes called state-space collapse, is observed in the pool-dependent networks.

2.3.1 Original model

Let \( Y_i^n(t) \) and \( Z_j^n(t) \) be, respectively, the number of class-\( i \) customers in the queue and the number of idle servers in pool \( j \), at time \( t \). Denote by \( A_i^n \) the arrival process of class-\( i \) customers, which is a Poisson process of rate \( \lambda_i^n \). Let \( S_{ij}^n \) be a Poisson process with rate \( \mu_{ij}^n \) and assume that the processes \( S_{ij}^n \) are mutually independent and independent of the arrival processes \( A_i^n \). Similarly, let \( R_i^n \) be Poisson processes of rate \( \theta_i^n \), which are independent of each other and of the processes \( A_i^n \) and \( S_{ij}^n \).

Let \( \Psi_{ij}^n(t) \) be the number of class-\( i \) customers served in pool \( j \) at time \( t \). Using the additivity of Poisson processes, the number of service completions in the interval
(0, t] of class-\(i\) customers by pool \(j\) can be represented \(S_{ij}^n(\int_0^t \Psi_{ij}^n(u)du)\). Likewise, since \(\int_0^t Y_{ij}^n(u)du\) indicates the time up to \(t\) that class-\(i\) customers wait in the queue, \(R_{ij}^n(\int_0^t Y_{ij}^n(u)du)\) is equal, in the distribution, to the number of abandonments of class-\(i\) customers by time \(t\). Thus we have,

\[
X_i^n(t) = X_i^n(0) + A_i^n(t) - \sum_{j \in J} S_{ij}^n(\int_0^t \Psi_{ij}^n(u)du) - R_i^n(\int_0^t Y_{ij}^n(u)du), \quad i \in I \tag{2.19}
\]

as well as

\[
X_i^n(t) = Y_i^n(t) + \sum_{j \in J} \Psi_{ij}^n(t), \quad i \in I \tag{2.20}
\]

\[
N_j^n = Z_j^n(t) + \sum_{i \in I} \Psi_{ij}^n(t), \quad j \in J \tag{2.21}
\]

\[
Y_{ij}^n(t) \geq 0, \quad Z_{ij}^n(t) \geq 0, \quad \Psi_{ij}^n(t) \geq 0, \quad i \in I, \quad j \in J, \quad t \geq 0. \tag{2.22}
\]

The processes \(\Psi^n = (\Psi_{ij}^n)_{(i,j) \in I \times J}\) are regarded as scheduling control policy and assumed to be right-continuous, taking values in \(\mathbb{Z}_+\). We are interested in finding an optimal policy that minimizes the operational cost

\[
V^{n,\pi}(x) = \mathbb{E}_x \left[ \int_0^\infty e^{-\alpha t} L(Y^n(t)) \, dt \right]. \tag{2.23}
\]

for some function \(L : \mathbb{R}^I \to \mathbb{R}\), over all possible policies \(\pi = \{\Psi\}\).

Note that our problem is introduced (2.19) – (2.23) with preemptive control policies in mind. A policy is regarded as preemptive if the service to customers can be interrupted at any time and resumed at a later time, possibly in a different server pool. In contrast, under a non-preemptive policy, every customer must complete service with the server that is first assigned to the customer. Interestingly, these two versions are asymptotically equivalent in the QED regime. We refer to [14] for further explanations.

### 2.3.2 Diffusion model

We introduce the following scaling to capture the fluctuations around the static fluid:

\[
\hat{A}_i^n(t) = \frac{A_i^n(t) - \lambda_i^n t}{\sqrt{n}}, \quad \hat{S}_{ij}^n(t) = \frac{S_{ij}^n(nt) - n\mu_{ij}^n t}{\sqrt{n}}, \quad \hat{R}_i^n(t) = \frac{R_i^n(nt) - n\theta_i^n t}{\sqrt{n}}. \tag{2.24}
\]
Similarly, the processes representing states of the queueing system are centered about the static fluid model (2.8) and rescaled as below:

\[
\hat{X}_n^i(t) = \frac{X_n^i(t) - nx_i^*}{\sqrt{n}},
\]

\[
\hat{Y}_n^i(t) = \frac{Y_n^i(t)}{\sqrt{n}}, \quad \hat{Z}_j^n(t) = \frac{Z_j^n(t)}{\sqrt{n}},
\]

\[
\hat{\Psi}_{ij}^n(t) = \frac{\Psi_{ij}^n(t) - \psi_{ij}^* \sqrt{n}}{\sqrt{n}}.
\]

We also assume that there are constants \(x_i, i \in I\), such that the initial conditions satisfy

\[
\hat{X}_n^i(0) = \frac{X_n^i(0) - nx_i^*}{\sqrt{n}} \to x_i.
\]

As a result, the relations (2.19) - (2.22) can be presented in the new form:

\[
\hat{X}_n^i(t) = \hat{X}_n^i(0) + \hat{W}_n^i(t) - \sum_{j \in J} \mu_{ij} \int_0^t \hat{\Psi}_{ij}^n(u)du - \theta_i^n \int_0^t \hat{Y}_n^i(u)du
\]

\[
\hat{Y}_n^i(t) = \sum_{j \in J} \hat{\Psi}_{ij}^n(t) = \hat{X}_n^i(t),
\]

\[
\hat{Z}_j^n(t) + \sum_{i \in I} \hat{\Psi}_{ij}^n(t) = 0,
\]

\[
\hat{Y}_n^i(t) \geq 0, \quad \hat{Z}_j^n(t) \geq 0, \quad i \in I, \quad j \in J, \quad t \geq 0
\]

where

\[
\hat{W}_n^i(t) = \hat{A}_i^n(t) - \sum_{j \in J} \hat{S}_{ij}^n \left( \frac{1}{n} \int_0^t \Psi_{ij}^n(u)du \right) - \hat{R}_i^n \left( \frac{1}{n} \int_0^t Y_{i}^n(u)du \right) + \left( \frac{\lambda_i^n}{\sqrt{n}} - \sqrt{n} \sum_{j \in J} \mu_{ij} \psi_{ij}^* \right) t.
\]

It can be shown, for each \(i\), that regardless of the scheduling policy, \(\hat{W}_n^i\) converges weakly to a Brownian motion \(\hat{W}_i(t)\) with a certain constant drift and variance. Therefore, by formally taking limits as \(n \to \infty\) and denoting the weak limit of
(\(\hat{X}^n, \hat{Y}^n, \hat{Z}^n, \hat{\Psi}^n, \hat{W}^n\)) by \((X, Y, Z, \Psi, W)\), we obtain diffusion equations as below.

\[
X_i(t) = x_i + \hat{W}_i(t) - \sum_{j \in J} \mu_{ij} \int_0^t \Psi_{ij}(u)du - \theta_i \int_0^t Y_i(u)du, \quad i \in I
\]  
(2.34)

\[
\sum_{j \in J} \Psi_{ij}(t) = X_i(t) - Y_i(t), \quad i \in I
\]  
(2.35)

\[
\sum_{i \in I} \Psi_{ij}(t) = -Z_j(t), \quad j \in J
\]  
(2.36)

\[
Y_i(t) \geq 0, \quad Z_j(t) \geq 0, \quad i \in I, \quad j \in J
\]  
(2.37)

Similar to (2.23), for a certain policy \(\pi = \{\Psi\}\), we introduce the cost function

\[
V^\pi(x) = \mathbb{E}_x^\pi \int_0^\infty e^{-\alpha t} L(Y(t))dt.
\]  
(2.38)

Atar, Mandelbaum and Shaikhet showed in [17] that the solution to the diffusion control problem (2.38) \(\sup_{\pi \in \Pi} V^\pi(x)\) dictates the optimal policy for the pre-limit control problem (2.23) \(\sup_{\pi \in \Pi} V^{n, \pi}(x)\).

### 2.3.3 Dimension reduction of pool-dependent models

For pool-dependent models, it was shown in [17] that the set of all possible policies can be restricted to work-conserving policies, i.e., the policies satisfying

\[
Z_e^n \wedge Y_e^n \equiv 0.
\]  
(2.39)

In such a case, we can observe an interesting dimension reduction [18]. In particular, the controlled process (generally \(I\)-dimensional) becomes one-dimensional, with the total number of customers \(\sum_{i \in I} X_i\) being the only quantity of interest, which we elaborate below.

By summing equations (2.34) over all \(i\)’s, we obtain

\[
X_e(t) = x_e + \hat{W}_e(t) + \sum_{j \in J} \mu_j \int_0^t Z_j(u)du - \sum_{i \in I} \theta_i \int_0^t Y_i(u)du.
\]  
(2.40)

From (2.35) and (2.36), we get \(X_e(t) = Y_e(t) - Z_e(t)\). Then, using (2.26), (2.32) and
(2.39), \(Y_e(t)\) and \(Z_e(t)\) can be represented as

\[ Y_e(t) = X_e^+(t), \quad Z_e(t) = X_e^-(t). \tag{2.41} \]

After that, we can define a process \(U = (w, v)\) taking values in

\[ A = \{(w, v) \in \mathbb{R}^I \times \mathbb{R}^J : w_i, v_j \geq 0, w_e = v_e = 1\}, \tag{2.42} \]

so that for all \(t \geq 0\),

\[ Y_i(t) = w_i(t)X_e^+(t), \quad Z_j(t) = v_j(t)X_e^-(t). \tag{2.43} \]

Intuitively, \(w\) represents the fraction of total queue length distributed in each class, while \(v\) indicates the fraction of total idleness assigned to each server pool. Rewrite (2.40):

\[ X_e(t) = x_e + \bar{W}_e(t) + \int_0^t [\mu \cdot v(u)]X_e^-(u)du - \int_0^t [\theta \cdot w(u)]X_e^+(u)du. \tag{2.44} \]

Together with the rewritten version of (2.38),

\[ V^\pi(x_e) = \mathbb{E}_x^\pi \int_0^\infty e^{-\alpha t}L\left(w(t) \cdot X_e^+(t)\right)dt \tag{2.45} \]

we get a diffusion control problem \(\sup_{\pi} V^\pi(x_e)\), where the action will depend on the sum \(X_e\) only.

Given the values of \(X_e(t)\), as well as \(w(t), v(t)\), the scheduling policy \(\{\Psi(t)\}\) can be uniquely determined from (2.35) - (2.36). In what follows we explicitly derive the controlled diffusions for our networks of interest.

**V model**

In a two-class V model, \(\mathcal{I} = \{1, 2\}\) and \(\mathcal{J} = \{1\}\):

\[ Y_1(t) = w_1(t)X_e^+(t), \quad Y_2(t) = w_2(t)X_e^+(t), \tag{2.46} \]

\[ Z_1(t) = X_e^-(t). \tag{2.47} \]

\[ \Psi_{11}(t) = X_1(t) - Y_1(t), \quad \Psi_{21}(t) = X_2(t) - Y_2(t), \quad \Psi_{11}(t) + \Psi_{21}(t) = -Z_1(t). \tag{2.48} \]
As a result, the equation (2.44) is simplified to

\[ X_e(t) = x_e + W_e(t) + \mu \int_0^t X_e^{-}(u)du - \int_0^t (\theta_1 w_1(u) + \theta_2 w_2(u)) X_e^{+}(u)du. \quad (2.49) \]

**N model**

In a N model, \( I = \{1, 2\} \) and \( J = \{1, 2\} \). Assume that pool 1 serves customers of class 1, and pool 2 serves customers of both classes. In this case for any \( t \geq 0 \),

\[
Y_1(t) = w_1(t)X_e^{+}(t), \quad Y_2(t) = w_2(t)X_e^{+}(t), \quad (2.50)
\]

\[
Z_1(t) = v_1(t)X_e^{-}(t), \quad Z_2(t) = v_2(t)X_e^{-}(t), \quad (2.51)
\]

\[
\Psi_{11}(t) + \Psi_{12}(t) = X_1(t) - Y_1(t), \quad \Psi_{22}(t) = X_2(t) - Y_2(t), \quad (2.52)
\]

\[
\Psi_{12}(t) + \Psi_{22}(t) = -Z_2(t), \quad \Psi_{11}(t) = -Z_1(t). \quad (2.53)
\]

Consequently, the equation (2.44) is simplified to

\[ X_e(t) = x_e + W_e(t) + \int_0^t (\mu_1 v_1(u) + \mu_2 v_2(u)) X_e^{-}(u)du - \int_0^t (\theta_1 w_1(u) + \theta_2 w_2(u)) X_e^{+}(u)du. \quad (2.54) \]

**Further simplifications of the control space**

It has been shown in [17], using the comparison’s principle, that if the cost function does not include idleness \( X_e^{-} \), taking \( v_{j^*} \equiv 1 \) (and \( v_j \equiv 0 \) for all \( j \neq j^* \)) for \( j^* = \arg \min \{\mu_j, j \in J\} \) is optimal for idleness allocation control \( v \).

In Chapter 3, we will investigate the aforementioned control problem by applying Markov decision processes. It will be shown that, in the QED heavy traffic regime, the optimal policy indeed depends on the value of the sum \( X_e^n \) only. We will also gain some intuition regarding the form of the optimal policy.
Chapter 3

Markov Decision Process

3.1 Introduction

A Markov decision process (MDP) is a controlled stochastic process that satisfies the Markov property with costs associated to each state transition. A Markov decision problem consists of a MDP and a performance criterion. A solution to a Markov decision problem is called a policy, which determines the optimal control actions according to the performance criterion. MDP has been applied to model and solve decision-making problems under uncertainty in various fields, such as operations research, economics, combinatorial optimization, and the social sciences [27].

In this chapter, we first briefly review the theories of MDP, along with the algorithms often used to solve a Markov decision problem. Then, we present the optimal policies for control problems of V model, N model and X model by using MDP.

3.1.1 Preliminaries

A Markov decision process is characterized by four elements:

\[ \{ S, A, q(j|i, a), c(i, a) \} \]

(3.1)

Here state space \( S \) is the set of all states of the system; action space \( A \) is the set of all possible actions; \( q(j|i, a) \) is the transition rate from state \( i \) to state \( j \) under action \( a \); \( c(i, a) \) is the cost for taking action \( a \) at state \( i \). In this chapter, we focus on finite state and action space and nonnegative cost functions.

A policy is a mapping from states to actions. If the policy is independent of time, it is called stationary. Let \( F \) denote the set of stationary policies.
Several performance criteria are commonly used to evaluate the policy, such as the finite-horizon expected cost, the infinite-horizon expected discount cost and the long-run expected average cost [28]. We are mainly interested in the infinite-horizon expected discount cost: for each policy $f \in \mathcal{F}$ and each initial state $x(0) = i$,

$$V_{\alpha}(i, f) = \mathbb{E}_{i}^f \left[ \int_{0}^{\infty} e^{-\alpha t} c(x(t), f) dt \right], \quad (3.2)$$

where $x(t)$ is the state of the system at time $t$ and $\alpha > 0$ is the discount factor.

Then the corresponding Markov decision problem is defined as below. Determine a policy $f^* \in \mathcal{F}$ such that

$$V_{\alpha}(i, f^*) = \min_{f \in \mathcal{F}} V_{\alpha}(i, f) =: V_{\alpha}^*(i) \quad \forall i \in S. \quad (3.3)$$

The basis for some practical algorithms that used to solve Markov decision problems is the optimality equation introduced in the following theorems (see [28] for more details).

**Theorem 3.1.** The optimal discount cost $V_{\alpha}^*(i)$ satisfies the discount-cost optimality equation below,

$$V_{\alpha}^*(i) = \min_{a \in A(i)} \left\{ \frac{c(i, a)}{\alpha + q_i(a)} + \frac{1}{\alpha + q_i(a)} \sum_{j \neq i} V_{\alpha}^*(j) q(j|i, a) \right\} \quad \forall i \in S, \quad (3.4)$$

where $q_i(a) = -q(i|i, a) \geq 0$ and $A(i)$ is the set of actions available when the state of the system is $i \in S$.

**Theorem 3.2.** Suppose that the optimal discount cost $V_{\alpha}^*(i) < \infty$ for all $i \in S$. Then optimality equation (3.4) is equivalent to the following optimality equation:

$$\alpha V_{\alpha}^*(i) = \min_{a \in A(i)} \left\{ c(i, a) + \sum_{j \in S} V_{\alpha}^*(j) q(j|i, a) \right\} \quad \forall i \in S. \quad (3.5)$$

### 3.1.2 Value iteration algorithm

The value iteration algorithm is a successive approximation algorithm for Markov decision problem devised by Bellman [29]. Define an operator $T$ as follows: for any
nonnegative function $u$ on $S$,

$$Tu(i) = \min_{a \in A(i)} \left\{ \frac{c(i, a)}{\alpha + q_i(a)} + \frac{1}{\alpha + q_i(a)} \sum_{j \neq i} u(j)q(j|i, a) \right\} \quad \forall i \in S \quad (3.6)$$

**Theorem 3.3.** Assume that continuity-compactness condition holds. Let $U^*_0 = 0$ and $U^*_{n+1} = TU^*_n$ for $n \geq 0$. Then,

1. $\{U^*_n\}$ is nondecreasing in $n \geq 0$, and $\lim_{n \to \infty} U^*_n = V^*_\alpha$.

2. Let $f_n \in \mathcal{F}(n \geq 0)$ be such that

$$U^*_{n+1}(i) = \min_{a \in A(i)} \left\{ \frac{c(i, a)}{\alpha + q_i(a)} + \frac{1}{\alpha + q_i(a)} \sum_{j \neq i} U^*_n(j)q(j|i, a) \right\}$$

$$= \frac{c(i, f_n(i))}{\alpha + q_i(f_n(i))} + \frac{1}{\alpha + q_i(f_n(i))} \sum_{j \neq i} U^*_n(j)q(j|i, f_n(i)) \quad (3.7)$$

for all $i \in S$. Then the limit point of $\{f_n\}$ is a discount-cost optimal stationary policy.

The continuity-compactness condition (Assumption 4.12, page 64 in [28]) guarantees the existence of a discount-cost optimal policy.

Theorem 3.3 suggests the cost functions that computed by iterations based on the value operator $T$ converge to the optimal cost function in the limit. In addition, the policies that associated with the successive cost functions also converge to the optimal policy in a finite number of iterations (please refer to [30] for detailed discussion).

The value iteration algorithm is described as follows:

1. Set $k = 0$ and take vector $V_k = 0$.

2. Loop:

   (a) Obtain $V_{k+1}(i) = \min_{a \in A(i)} \left\{ \frac{c(i, a)}{\alpha + q_i(a)} + \frac{1}{\alpha + q_i(a)} \sum_{j \neq i} V_k(j)q(j|i, a) \right\}$ for all $i \in S$.

   (b) If $\max_{i \in S}[V_{k+1}(i) - V_k(i)]$ is sufficiently small, stop; otherwise, increment $k$ by 1 and repeat the loop.

3. Return policy $\{a \in A(i) : i \in S\}$ for all $i \in S$. 
3.1.3 Policy iteration algorithm

Another well-known algorithm for solving MDPs is designed by Howard [31] and known as policy iteration. There are two phases involved in the policy iteration algorithm: policy evaluation and policy improvement. First, we introduce a theorem since it provides a method of evaluating policy.

**Theorem 3.4.** For a finite Markov decision problem, \( V_\alpha(f) \) is a unique bounded solution to the equation

\[
\alpha u(i) = c(i, f) + \sum_{j \in S} u(j)q(j|i, f) \quad \forall i \in S \tag{3.8}
\]

for every \( f \in \mathcal{F} \).

Next, we define an improvement policy. For every given \( f \in \mathcal{F}, i \in S, \) and \( a \in A(i), \) let

\[
D_f(i, a) = c(i, a) + \sum_{j \in S} V_\alpha(j, f)q(j|i, a) \tag{3.9}
\]

and

\[
E_f(i) = \{a \in A(i) : D_f(i, a) < \alpha V_\alpha(i, f)\}. \tag{3.10}
\]

Then, an improvement policy \( h \in \mathcal{F} \) is defined as follows:

\[
h(i) \in E_f(i) \quad \text{if} \quad E_f(i) \neq \emptyset \quad \text{and} \quad h(i) = f(i) \quad \text{if} \quad E_f(i) = \emptyset \tag{3.11}
\]

The following theorem explains the reason that policy \( h \) is an improvement of \( f \).

**Theorem 3.5.** For any given \( f \in \mathcal{F} \), let \( h \in \mathcal{F} \) be defined as in (3.11) and \( h \neq f \). Then \( V_\alpha(f) \succeq V_\alpha(h) \).

We state the policy iteration algorithm as below:

1. Select an arbitrary \( f \in \mathcal{F} \). Set \( k = 0 \) and take \( f_k = f \).

2. Loop:
   
   (a) (Policy evaluation) Obtain \( V_\alpha(f_k) \) by solving (3.8), which is equal to \( V_\alpha(f_k) = [\alpha I - Q(f_k)]^{-1}c(f_k) \).
   
   (b) (Policy improvement) Obtain an improvement policy of \( f_k \) from (3.11) and set as \( f_{k+1} \).
(c) If \( f_{k+1} = f_k \), stop; otherwise, increment \( k \) by 1 and repeat the loop.

3. Return policy \( f_k \).

### 3.2 Optimal control of V model

In this section, we study the control problem of a Markovian two-class V model (see Figure 3.1) by interpreting it as a Markov decision problem. In this model, we assume that the arrival rate of class-\( i \) customers is \( \lambda_i \); the abandonment rate of class-\( i \) customers is \( \theta_i \); the service rates of both classes are \( \mu \), because they are pool-dependent; the single server pool consists of \( N \) statistically identical and independent servers (\( i \in \mathcal{I} = \{1, 2\} \)).

![Figure 3.1: V model](image)

Let \( c_1 \) and \( c_2 \) denote the holding cost rates of class-1 and class-2 customers, respectively. The cost per unit time at time \( t \) is defined as \( c_1 q_1(t) + c_2 q_2(t) \), where \( q_i(t) \) represents the number of queued class-\( i \) customers at time \( t \). There are a variety of ways to schedule the waiting customers. Our concern is to find the policy that minimizes the infinite-horizon expected discount cost \( V_\alpha(x_1, x_2) = \mathbb{E} \left[ \int_0^\infty e^{-\alpha t} (c_1 q_1(t) + c_2 q_2(t)) dt \right] \).

The solution to this control problem is obvious when \( c_1 > c_2 \) and \( \theta_1 < \theta_2 \). It would be optimal to hold class-2 customers in the queue because they are cheaper and more likely to abandon. However, when \( c_1 > c_2 \) and \( \theta_1 > \theta_2 \), one must make a trade-off between the low cost rate and high abandonment rate. In other words, if
one maintains waiting population in class 1, the high abandonment rate is helpful to reduce the cost but the high cost rate is unfavorable; similarly, if one keeps customers of class 2 waiting, one will enjoy the low cost rate but also have to accept the low abandonment rate.

The explicit solution of this problem by using diffusion control model has not been provided. We interpret the problem as a Markov decision problem and apply the policy iteration algorithm to solve the optimal control policy. The algorithm was implemented in MATLAB, and the code is given in Appendix A.1.

### 3.2.1 Markov decision problem

First of all, we specify the basic elements (3.1) of the MDP associated with the above V model.

**State space**

Let \( x_i(t) \) denote the total number of class-\( i \) customers in the system at time \( t \) (\( i \in \{1, 2\} \)). The state of the system at time \( t \) can be described by a two-dimensional vector \((x_1(t), x_2(t))\). To simulate a queueing system with infinite waiting capacity, the upper bounds of \( x_1 \) and \( x_2 \) are set as \( N + O(N^{2/3}) \), which was shown in (2.14) that would be reached with very small probability in the QED regime. So we denote by \( S \) the state space and set

\[
S = \{(x_1, x_2) | 0 \leq x_i \leq N + O(N^{2/3}), \quad i \in \mathcal{I}\}.
\]  

**Action space**

Considering preemptive, work-conserving and stationary policies for this control problem, we define \((s_1, s_2)\) as a control action of state \((x_1, x_2)\). \( s_i \) indicates the number of class-\( i \) customers in service \( (i \in \mathcal{I}) \). Then, \( x_i - s_i \) is the queue length of class-\( i \) customers. Let \( A(x_1, x_2) \) denote the set of available actions at state \((x_1, x_2) \in S\).

\[
A(x_1, x_2) = \{(s_1, s_2) | s_1 + s_2 = (x_1 + x_2) \land N, 0 \leq s_i \leq x_i, i \in \mathcal{I}\}
\]  

In Chapter 2, we show by (2.49) that this control problem can be simplified to one-dimensional, with \( x_1 + x_2 \), the total number of customers, being the only quantity
of interest. In other words, the control policy can be uniquely determined when given
\(x_1 + x_2\) and \((w_1, w_2)\), the fraction of total queued customers. By definition,
\[
    w_1 = 1 - w_2 = \frac{x_1 - s_1}{x_1 + x_2 - N} \mathbb{1}_{\{x_1 + x_2 > N\}},
\]
(3.14)
where \(s_1 \in [0 \lor (N - x_2), x_1 \land N]\).

Note that in the QED heavy traffic regime, \(x_1\) fluctuates within \([nx_1^* - n^{1+\gamma}, nx_1^* + n^{1+\gamma}]\), which indicates \(x_1 \land N = x_1\). Likewise, \(0 \lor (N - x_2) = N - x_2\). Therefore, \(0 \leq w_1 \leq 1\) and its extreme values can always be achieved.

**Transition rates**

The transition rate from state \((x_1, x_2)\) to state \((x'_1, x'_2)\) under action \(a = (s_1, s_2)\) are represented as follows:
\[
    q((x'_1, x'_2) | (x_1, x_2), a = (s_1, s_2)) =
\]
\[
    \begin{cases}
    \lambda_1 & \text{if } x'_1 = x_1 + 1, x'_2 = x_2, \\
    \lambda_2 & \text{if } x'_1 = x_1, x'_2 = x_2 + 1, \\
    \mu_1 s_1 + (x_1 - s_1) \theta_1 & \text{if } x'_1 = x_1 - 1, x'_2 = x_2, \\
    \mu_2 s_2 + (x_2 - s_2) \theta_2 & \text{if } x'_1 = x_1, x'_2 = x_2 - 1, \\
    -\lambda_1 - \lambda_2 - \mu_1 s_1 - (x_1 - s_1) \theta_1 - \mu_2 s_2 - (x_2 - s_2) \theta_2 & \text{if } x'_1 = x_1, x'_2 = x_2, \\
    0 & \text{otherwise.}
    \end{cases}
\]
(3.15)

**Cost function**

Considering linear holding cost, we denote \(c_i\) the cost of keeping a class-\(i\) customer waiting for a unit time \((i \in \mathcal{I})\). Then, for policy \(f = \{(s_1(t), s_2(t))\}\), cost per unit time at time \(t\) is
\[
    c(x_1(t), x_2(t), f) = c_1(x_1(t) - s_1(t)) + c_2(x_2(t) - s_2(t)).
\]
(3.16)

We also need to specify the performance criterion of the Markov decision problem.
Performance criterion

For each policy $f \in \mathcal{F}$ and each initial state $(x_1, x_2) \in S$, the infinite-horizon expected discount cost is

$$V_\alpha(x_1, x_2, f) = \mathbb{E} \left[ \int_0^\infty e^{-\alpha t} c(x_1(t), x_2(t), f) dt \right].$$

(3.17)

Our goal is to determine a policy $f^* \in \mathcal{F}$ such that

$$V_\alpha(x_1, x_2, f^*) = \min_{f \in \mathcal{F}} V_\alpha(x_1, x_2, f) := V_\alpha^*(x_1, x_2).$$

(3.18)

3.2.2 Numerical analysis

When the parameters of the above model are taken appropriate values, the optimal policy can be obtained by using MATLAB programs. We set parameters as follows.

Parameters Setting

- Discount factor $\alpha = 0.9$.
- Consider the QED regime, we set $\mu = 6$, $N = 50$ and $\lambda_1 = \lambda_2 = 150$.
- $\theta_1 = 5$, $\theta_2 = 1$. We need to ensure $\max(\theta_1, \theta_2) \leq \mu$, because otherwise it may be optimal to let customers abandon rather than to provide them service.
- $c_1 = 11$, $c_2 = 5$.
- Set the state space $S = \{(x_1, x_2) | 0 \leq x_1, x_2 \leq 80\}$, in which $80 > N + 2N^{2/3} \approx 77$.

To better visualize the optimal policy generated by the programs, we mark the states showing different control actions with different shapes and colors.

As shown in Figure 3.2 (a), the x-axis and y-axis represent $x_1$ and $x_2$, respectively. In other words, each point represents a state $(x_1, x_2) \in S$. For states $\{(x_1, x_2) | x_1 + x_2 \leq N\}$, $\{(s_1, s_2) | s_1 = x_1, s_2 = x_2\}$ is the only available action, so it is unnecessary to concern oneself with their optimal actions. We mark these states with blue ”+”. For states with $s_1$ taken its maximum $x_1 \wedge N$, $w_1$ is taken its minimum, so the optimal action is to keep class-2 customers waiting. We mark such states with pink ”°".
Likewise, for states with $s_1$ taken its minimum $0 \lor (N - x_2)$, the optimal action is to hold class-1 customers in the queue. We mark these states with red "/\".*"/.

As suggested by the claim (2.11) in Chapter 2, a rectangle window around the static fluid model should be set as our observation region:

$$
\{(x_1, x_2) | x_1 \in [nx_1^* - n^{1+\gamma_1}, nx_1^* + n^{1+\gamma_1}], x_2 \in [nx_2^* - n^{1+\gamma_2}, nx_2^* + n^{1+\gamma_2}]\}. \tag{3.19}
$$

With our parameters, $n = 50$, $x_1^* = x_2^* = 0.5$.

Besides, we found the optimal discount costs $V_\alpha^*(x_1, x_2)$ of the states having the same $x_1 + x_2$ are very close to each other. So we plot their relationship in Figure 3.2 (b), in which the x-axis and y-axis are $x_1 + x_2$ and $V_\alpha^*(x_1, x_2)$, respectively.

**The optimal policy depends on $x_1 + x_2$**

As can be seen, Figure 3.2-3.5 are plotted under different cost rate $c_1$. Figure 3.3 (a) shows that, when $c_1$ is small, the optimal policy is to keep waiting population in class 1. This is intuitively clear because it is more economical to keep the less patient
Figure 3.3: Optimal policy for V model: $c_1 = 7$

Figure 3.4: Optimal policy for V model: $c_1 = 14$
(a) Optimal policy  (b) Relation between $V^*_\alpha(x_1, x_2)$ and $x_1 + x_2$

Figure 3.5: Optimal policy for V model: $c_1 = 16$

customers waiting if they are very cheap to hold.

However, if the cost rate $c_1$ becomes higher, the optimal policy indicates that one should keep waiting population in class 2 at some states (pink region) and to class 2 at the others (red region). Within the observation region, there is a boundary separating the pink and red regions, which is similar to a straight line $x_1 + x_2 = k$ ($k \geq N$). As suggested by Figure 3.2 and 3.4, $k$ becomes bigger when $c_1$ increases.

If $c_1$ is sufficiently big (see Figure 3.5), the optimal policy is to hold class-2 customers in the queue. Obviously, it is better to serve class-1 customers as soon as possible if their holding cost is much higher than class 2, no matter how often they abandon the system.

To sum up, one can conclude that the optimal policy depends on the total number of customers $x_1 + x_2$ only. There is a threshold value of $x_1 + x_2$ that determines the change of optimal action. Moreover, the threshold value is related to the cost rates $c_1$ and $c_2$. 
The optimal discount cost depends on $x_1 + x_2$

As shown in Figure 3.2 (b) - 3.5 (b), the optimal discount costs $V_\alpha^*(x_1, x_2)$ with the same $x_1 + x_2$ converge to one point in large scale, which indicates that $V_\alpha^*(x_1, x_2)$ is probably a function of $x_1 + x_2$.

In addition, the colors representing different optimal action separate well, which also demonstrates that the optimal policy depends on $x_1 + x_2$. For example, in Figure 3.2 (b), for states $\{(x_1, x_2)|50 < x_1 + x_2 < 60\}$, the optimal action is to keep class-2 customers waiting (pink region); for states $\{(x_1, x_2)|x_1 + x_2 \geq 60\}$, it is optimal to hold class-1 customers in the queue (red region).

Relation between $\frac{dV_\alpha^*(x_1, x_2)}{d(x_1+x_2)}$ and $\frac{c_1-c_2}{\theta_1-\theta_2}$

According to the conjecture proposed by Shaikhet [18], the optimal policy is decided by the relation between $\frac{c_1-c_2}{\theta_1-\theta_2}$ and the derivative of $V_\alpha^*(x_1, x_2)$ with respect to $x_1 + x_2$. To check the conjecture, we take the minimum among the costs with the same $x_1 + x_2$ as a representative of $V_\alpha^*(x_1, x_2)$ and calculate the derivative as below:

$$\frac{dV_\alpha^*(x_1, x_2)}{d(x_1+x_2)} := V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1).$$

In Figure 3.6, x-axis represents $x_1 + x_2$. We take $x_1 + x_2 > N$ because our main concern is the distribution of waiting customers. The blue lines describe the derivatives under different $c_1$s, while the red lines indicate the corresponding $\frac{c_1-c_2}{\theta_1-\theta_2}$.

By comparing Figure 3.6 and Figure 3.2 - 3.5, one can find an accordance between them. For example, in Figure 3.6 (b), the derivative exceeds $\frac{c_1-c_2}{\theta_1-\theta_2} = 1.50$ when $x_1 + x_2$ reaches 60; while in Figure 3.2, the threshold value of $x_1 + x_2$ is also 60. Therefore, the optimal policy can be described as follows: when $V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1) \leq \frac{c_1-c_2}{\theta_1-\theta_2}$, it is optimal to keep waiting population in class 2; when $V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1) > \frac{c_1-c_2}{\theta_1-\theta_2}$, it is optimal to keep waiting population in class 1.

In addition, the slight decrease of the derivatives at the end of the blue line in Figure 3.6 (d) suggests that the optimal expected cost $V_\alpha^*(x_1, x_2)$ is not necessary a convex function of $x_1 + x_2$. As a result, there might be more than one threshold in the optimal policy.
Figure 3.6: V model: relation between $dV^*_{\alpha}(x_1,x_2)$ and $\frac{c_1-c_2}{\theta_1-\theta_2}$

3.2.3 Proof

In this section, we prove that the optimal policy for the above V model is “bang-bang”; that is, the control variable $u_1$ (or equivalently, $s_1$) can only take its extreme values. Decisions regarding whether to take the maximum or the minimum depend on the relation between $\frac{c_1-c_2}{\theta_1-\theta_2}$ and $V^*_\alpha(x_1+x_2) - V^*_\alpha(x_1 + x_2 - 1)$.

**Theorem 3.6.** For a pool-dependent V model, the optimal expected cost $V^*_\alpha(x_1,x_2)$ is a nondecreasing function of the total number of customers $x_1 + x_2$.

- When $V^*_\alpha(x_1+x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{c_1-c_2}{\theta_1-\theta_2}$, it is optimal to keep waiting population in the class $i^*$, where $i^* = \arg\min\{\theta_i, \ i \in I\}$;

- When $V^*_\alpha(x_1+x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{c_1-c_2}{\theta_1-\theta_2}$, it is optimal to keep waiting population in the class $i^*$, where $i^* = \arg\max\{\theta_i, \ i \in I\}$.
\textbf{Proof:} First, we show that $V^*_\alpha(x_1, x_2)$ is a non-decreasing function of $x_1 + x_2$. From (3.14), the control action $(s_1(t), s_2(t))$ is uniquely determined by $x_1(t) + x_2(t)$ when given $(w_1(t), w_2(t))$; that is to say, the dynamic of controlling the system depends on the sum $x_1(t) + x_2(t)$ rather than $x_1(t)$ and $x_2(t)$. Besides, by (3.14) and (3.16),
\begin{equation}
  c(x_1(t), x_2(t), f) = [c_1 w_1(t) + c_2 (1 - w_1(t))](x_1(t) + x_2(t) - N)1_{(x_1(t) + x_2(t) > N)}.
\end{equation}
So the cost associated to each state transition depends only the sum $x_1(t) + x_2(t)$ as well. Thus, the optimal discount cost $V^*_\alpha(x_1, x_2) = \min_{f \in F} E[\int_0^\infty e^{-\alpha t} c(x(t), x_2(t), f)dt]$ is a non-decreasing function of $x_1 + x_2$, the sum of initial state; that is,
\begin{equation}
  V^*_\alpha(x_1 - 1, x_2) = V^*_\alpha(x_1, x_2 - 1) := V^*_\alpha(x_1 + x_2 - 1).
\end{equation}
According to Theorem 3.2, for each state $(x_1, x_2) \in S$,
\begin{equation}
  \alpha V^*_\alpha(x_1, x_2) = \min_{(s_1, s_2) \in A(x_1, x_2)} \left\{ \sum_{(x'_1, x'_2) \in S} V^*_\alpha(x'_1, x'_2)q((x'_1, x'_2)|(x_1, x_2), a = (s_1, s_2)) + c_1(x_1 - s_1) + c_2(x_2 - s_2) \right\}.
\end{equation}
By substituting the transition rates (3.15),
\begin{equation}
  \alpha V^*_\alpha(x_1, x_2) = \min_{(s_1, s_2) \in A(x_1, x_2)} \left\{ c_1(x_1 - s_1) + c_2(x_2 - s_2) + \lambda_1 V^*_\alpha(x_1 + 1, x_2) \\
  + \lambda_2 V^*_\alpha(x_1, x_2 + 1) + [\mu s_1 + \theta_1(x_1 - s_1)]V^*_\alpha(x_1 - 1, x_2) \\
  + [\mu s_2 + \theta_2(x_2 - s_2)]V^*_\alpha(x_1, x_2 - 1) - [\lambda_1 + \lambda_2 + \mu s_1 \\
  + (x_1 - s_1)\theta_1 + \mu s_2 + (x_2 - s_2)\theta_2]V^*_\alpha(x_1, x_2) \right\} \\
  = \min_{(s_1, s_2) \in A(x_1, x_2)} \left\{ C + s_1[\mu - \theta_1](V^*_\alpha(x_1 + x_2 - 1) - V^*_\alpha(x_1, x_2)) - c_1 \\
  + s_2(\mu - \theta_2)(V^*_\alpha(x_1 + x_2 - 1) - V^*_\alpha(x_1, x_2)) - c_2 \right\},
\end{equation}
where $C$ is the part independent of $s_1$ and $s_2$.

By (3.13), $s_2 = (x_1 + x_2) \wedge N - s_1$. Then, for states $\{(x_1, x_2)|x_1 + x_2 \leq N\}$, $s_2 = x_2$; for states $\{(x_1, x_2)|x_1 + x_2 > N\}$, $s_2 = N - s_1$. When $x_1 + x_2 \leq N$, $(s_1, s_2) = (x_1, x_2)$ is the only available action. It is unnecessary to consider its optimal action.
When \( x_1 + x_2 > N \), by substituting \( s_2 = N - s_1 \) in (3.24),
\[
\alpha V^*_\alpha(x_1, x_2) = \min_{(s_1, s_2) \in A(x_1, x_2)} \{ C' + s_1[(\theta_1 - \theta_2)(V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1)) - (c_1 - c_2)] \}.
\] (3.25)

where \( C' = C + N[(\mu - \theta_2)(V^*_\alpha(x_1, x_2 - 1) - V^*_\alpha(x_1, x_2)) - c_2] \).

Notice that
\[
V^*_\alpha(x_1 + x_2) \geq V^*_\alpha(x_1 + x_2 - 1).
\] (3.26)

Therefore,

- if \( \theta_1 < \theta_2 \),
  1. when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{c_1 - c_2}{\theta_1 - \theta_2} \), one should take the minimum of \( s_1 \), i.e. \( s_1 = (N - x_2) \lor 0 \), which means to take the maximum of \( w_1 \). Thus, it is optimal to keep waiting population in class 1;
  2. when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{c_1 - c_2}{\theta_1 - \theta_2} \), one should take the maximum of \( s_1 \), i.e. \( s_1 = x_1 \land N \), which means to take the minimum of \( w_1 \). Thus, it is optimal to keep waiting population in class 2.

- if \( \theta_1 > \theta_2 \),
  1. when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{c_1 - c_2}{\theta_1 - \theta_2} \), one should take the maximum of \( s_1 \); that is, it is optimal to keep waiting population in class 2;
  2. when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{c_1 - c_2}{\theta_1 - \theta_2} \), one should take the minimum of \( s_1 \); that is, it is optimal to keep waiting population in class 1.

### 3.3 Optimal control of N model

A pool-dependent N model is a direct extension of the two-class V model studied in the previous section. As shown in Figure 3.7, pool 1, which consists of \( N_1 \) servers, serves class-1 customers with rate \( \mu_1 \); pool 2, which contains \( N_2 \) servers, serve customers of both class 1 and 2 with the same rate \( \mu_2 \).

For this N model, we are also interested in determining the optimal policy to minimize \( V_\alpha(x_1(t), x_2(t), f) = E[\int_0^\infty e^{-\alpha t}c(x_1(t), x_2(t), f)dt] \), the expected discount
cost of keeping customers waiting. The Markov decision problem associated with
this queueing model is similar to that of the above V model. It can be solved by a
modified policy iteration algorithm, for which the code is given in Appendix A.2.

3.3.1 Markov decision problem

State space

As suggested by (2.16) and (2.17) in Chapter 2, \(N_1 + N_2\) and \(N_2\) are the asymptotic
upper bounds of the number of class-1 customers and the number of class-2 customers,
respectively. Hence, to simulate a queueing system with infinite waiting capacity, we
define the state space

\[
S = \{(x_1, x_2) | 0 \leq x_1 \leq N_1 + N_2, \ 0 \leq x_2 \leq N_2\}. \tag{3.27}
\]

Action space

Considering preemptive, work-conserving and stationary policies, we designate the
following set \(A(x_1, x_2)\) as the action space for state \((x_1, x_2) \in S\):

\[
A(x_1, x_2) = \{(s_{11}, s_{12}, s_{22}) | s_{11} + s_{12} + s_{22} = (x_1 + x_2) \land (N_1 + N_2),
\ 0 \leq s_{ij} \leq x_i, \ i \in I, \ j \in J\}. \tag{3.28}
\]

Here \(s_{ij}\) indicates the number of class-\(i\) customers served by pool \(j\).
Notice that the simplified one-dimensional diffusion equation (2.54) contains two control variables \(\{(w, v) \in \mathbb{R}^I \times \mathbb{R}^J : w_i, v_j \geq 0, w_e = v_e = 1\}\). \(w\) and \(v\) represent the ratios of total queued customers and total idle servers, respectively. According to work-conservation, \(s_{11} = N_1\) when \(x_1 + x_2 > N_1 + N_2\), so

\[
\frac{x_1 - N_1 - s_{12}}{x_1 + x_2 - (N_1 + N_2)} \mathbb{I}_{\{x_1 + x_2 > N_1 + N_2\}}, \quad (3.29)
\]

where \(s_{12} \in [N_2 - x_2, (x_1 - N_1) \land N_2]\). And

\[
\frac{N_1 - s_{11}}{N_1 + N_2 - (x_1 + x_2)} \mathbb{I}_{\{x_1 + x_2 < N_1 + N_2\}}, \quad (3.30)
\]

where \(s_{11} \in [(x_1 + x_2 - N_2) \lor 0, N_1 \land x_1]\).

Note that in the QED heavy traffic regime, \(x_1\) fluctuates within \([nx_1^* - n^{\frac{1}{2}} + \gamma, nx_1^* + n^{\frac{1}{2}} + \gamma]\), which means \((x_1 - N_1) \land N_2 = x_1 - N_1\) and \(N_1 \land x_1 = N_1\). Likewise, \((x_1 + x_2 - N_2) \lor 0 = x_1 + x_2 - N_2\). Therefore, \(0 \leq w_1 \leq 1, 0 \leq v_1 \leq 1\), and their extreme values can always be achieved.

**Transition rates**

The transition rate from state \((x_1, x_2)\) to state \((x'_1, x'_2)\) under action \(a = (s_{11}, s_{12}, s_{22})\) is

\[
q((x'_1, x'_2)|(x_1, x_2), a = (s_{11}, s_{12}, s_{22})) =
\begin{cases}
\lambda_1 & \text{if } x'_1 = x_1 + 1, x'_2 = x_2, \\
\lambda_2 & \text{if } x'_1 = x_1, x'_2 = x_2 + 1, \\
\mu_1s_{11} + \mu_2s_{12} + (x_1 - s_{11} - s_{12})\theta_1 & \text{if } x'_1 = x_1 - 1, x'_2 = x_2, \\
\mu_2s_{22} + (x_2 - s_{22})\theta_2 & \text{if } x'_1 = x_1, x'_2 = x_2 - 1, \\
\rho & \text{if } x'_1 = x_1, x'_2 = x_2, \\
0 & \text{otherwise.}
\end{cases}
\quad (3.31)
\]

where \(\rho = -\lambda_1 - \lambda_2 - \mu_1s_{11} - \mu_2(s_{12} + s_{22}) - (x_1 - s_{11} - s_{12})\theta_1 - (x_2 - s_{22})\theta_2\).
Cost function

For policy $f = \{(s_{11}(t), s_{12}(t), s_{22}(t))\}$, cost per unit time at time $t$ is

$$c(x_1(t), x_2(t), f) = c_1(x_1(t) - s_{11}(t) - s_{12}(t)) + c_2(x_2(t) - s_{22}(t)).$$

(3.32)

3.3.2 Numerical analysis

In our MATLAB programs, parameters are set as below.

Parameters Setting

- Discount factor $\alpha = 0.9$.
- Consider the QED regime, $\mu_1 = 6$, $\mu_2 = 8$, $N_1 = 50$, $N_2 = 50$, $\lambda_1 = 500$ and $\lambda_2 = 200$.
- $\theta_1 = 5$, $\theta_2 = 1$.
- $c_1 = 11$, $c_2 = 5$.
- The state space is set as $S = \{(x_1, x_2)|0 \leq x_1 \leq 100, \ 0 \leq x_2 \leq 50\}$.

Same as above, states are highlighted with several shapes and colors in the figures we obtained. For states $\{(x_1, x_2)|x_1 + x_2 \leq N_1 + N_2\}$, the state will be marked with green "x" if its action is to take the minimum of $s_{11}$, which indicates to keep idleness in pool 1; the state will be marked with black "x" if the action is taking the maximum of $s_{11}$, which indicates to keep idleness in pool 2; the state will be marked with blue "+" if the action is neither of the above two. For states $\{(x_1, x_2)|x_1 + x_2 > N_1 + N_2\}$, the state will be marked with pink "o" if $s_{12}$ is taken the maximum, that is, one should keep class-2 customers waiting for being served by pool 2; the state will be marked with red "*" if $s_{12}$ is taken the minimum, that is, one should keep class-1 customers waiting for being served by pool 2; the state will be marked with blue "+" if $s_{12}$ is not taken its extreme values.

The rectangle windows in the following figures indicate the observation regions, which, as suggested by claim (2.11), should be around the static fluid model (2.8).
Figure 3.8: Optimal policy for N model: $c_1 = 6$

Figure 3.9: Optimal policy for N model: $c_1 = 8$

**Idleness is kept in the slower server pool**

As can be see in Figure 3.8-3.11, the optimal action of states $\{(x_1, x_2) | x_1 + x_2 \leq N_1 + N_2\}$ is to keep idle servers in pool 1. It is intuitively clear that when there are free servers in both pools, customers would choose the faster servers. With our parameters, servers in pool 2 is faster and will be kept busy. So idle servers should be kept in pool 1.
Figure 3.10: Optimal policy for N model: $c_1 = 9$

Figure 3.11: Optimal policy for N model: $c_1 = 12$

The optimal policy depends on $x_1 + x_2$

For states $\{(x_1, x_2)|x_1 + x_2 > N_1 + N_2\}$, there is a boundary separating states with different optimal actions. Within the observation region, the boundary is similar to a straight line $x_1 + x_2 = k$. When $c_1$ increases, $k$ becomes bigger. For example, when $c_1 = 9$ (see Figure 3.10), the optimal policy for states $\{(x_1, x_2)|100 < x_1 + x_2 < 106\}$ is approximately keeping class-2 customers waiting for available pool-2 servers; while for states $\{(x_1, x_2)|x_1 + x_2 \geq 106\}$, it is optimal to hold the waiting population in class 1. Above all, one can conjecture that the optimal policy is decided by $x_1 + x_2$, the
Figure 3.12: N model: relation between $dV^\ast(\alpha)(x_1, x_2)$ and $\frac{c_1 - c_2}{\theta_1 - \theta_2}$

total number of customers in the system. In addition, the threshold value of $x_1 + x_2$ depends on the cost rates $c_1$ and $c_2$.

**Relation between $\frac{c_1 - c_2}{\theta_1 - \theta_2}$ and $\frac{dV^\ast(\alpha)(x_1, x_2)}{d(x_1 + x_2)}$**

Similarly to the above V model, the optimal expected cost $V^\ast(\alpha)(x_1, x_2)$ of N model is shown to be a function of $x_1 + x_2$. We calculate the derivatives $\frac{dV^\ast(\alpha)(x_1, x_2)}{d(x_1 + x_2)} := V^\ast(\alpha)(x_1 + x_2) - V^\ast(\alpha)(x_1 + x_2 - 1)$ and compare them with $\frac{c_1 - c_2}{\theta_1 - \theta_2}$. Since our main concern is the distribution of queued customers, we only plot the derivatives when $x_1 + x_2 > N_1 + N_2$ in Figure 3.12.

The blue line shows the derivatives $\frac{dV^\ast(\alpha)(x_1, x_2)}{d(x_1 + x_2)}$ with respect to $x_1 + x_2 \in [101, 143]$, while the red line indicates the value of $\frac{c_1 - c_2}{\theta_1 - \theta_2}$. Figure 3.12 (a), (b) and (d) coincide with Figure 3.8, 3.9 and 3.11. They demonstrate that when $V^\ast(\alpha)(x_1 + x_2) - V^\ast(\alpha)(x_1 +
$x_2 - 1) \leq \frac{c_1 - c_2}{\theta_1 - \theta_2}$, it is optimal to keep waiting population in class 2; when $V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{c_1 - c_2}{\theta_1 - \theta_2}$, the optimal action is to keep waiting customers in class 1. Figure 3.12(c) does not completely agree with Figure 3.10 because when $x_1 + x_2 > 130$, the derivatives become less than $\frac{c_1 - c_2}{\theta_1 - \theta_2}$, but Figure 3.10 does not show the change of optimal policy. We consider this an error due to the restriction of MDP programs. Figure 3.12 also suggests that $V^*_\alpha(x_1, x_2)$ is not necessarily a convex function of $x_1 + x_2$.

### 3.3.3 Proof

In this section, we provide a proof to show the “bang-bang” policy presented above is optimal for the control of N model. The policy includes two parts: first, it is optimal to keep idle servers in pool 1, that is, to take the maximum of control variable $v_1$ (or equivalently, the minimum of $s_{11}$); second, one should keep waiting population either in class 1 or class 2, that is, $w_1$ (or equivalently, $s_{12}$) should only take its extreme values. Whether to take the maximum or minimum of $w_1$ (or $s_{12}$) is decided by the relation between $\frac{c_1 - c_2}{\theta_1 - \theta_2}$ and $\frac{dV^*_\alpha(x_1, x_2)}{dx_1 + x_2}$.

**Theorem 3.7.** For a pool-dependent N model, the optimal expected cost $V^*_\alpha(x_1, x_2)$ is a non-decreasing function of the total number of customers $x_1 + x_2$.

- **When** $x_1 + x_2 \leq N_1 + N_2$, it is optimal to keep idleness in pool $j^*$, where $j^* = \text{arg min}\{\mu_j, j \in J\}$.

- When $x_1 + x_2 > N_1 + N_2$,
  
    1. if $V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{c_1 - c_2}{\theta_1 - \theta_2}$, it is optimal to keep waiting population in the class $i^*$, where $i^* = \text{arg min}\{\theta_i, i \in I\}$;
    
    2. if $V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{c_1 - c_2}{\theta_1 - \theta_2}$, it is optimal to keep waiting population in the class $i^*$, where $i^* = \text{arg max}\{\theta_i, i \in I\}$.

**Proof:** First, we show that $V^*_\alpha(x_1, x_2)$ is a non-decreasing function of $x_1 + x_2$. From (3.29) and (3.30), the control action $(s_{11}(t), s_{12}(t), s_{22}(t))$ can be uniquely determined by $x_1(t) + x_2(t)$ when given $w(t)$ and $v(t)$; that is to say, the dynamic of controlling the system depends on the sum $x_1(t) + x_2(t)$ rather than $x_1(t)$ and $x_2(t)$. Besides, by
So the cost associated to each state transition depends only on the sum $x_1(t) + x_2(t)$ as well. Consequently, the optimal discount cost $V_{\alpha}^*(x_1, x_2) = \min_{f \in F} \mathbb{E}[\int_0^\infty e^{-\alpha t} c(x_1(t), x_2(t), f) dt]$ is a non-decreasing function of $x_1 + x_2$, the sum of initial state; that is,

$$V_{\alpha}^*(x_1 - 1, x_2) = V_{\alpha}^*(x_1, x_2 - 1) := V_{\alpha}^*(x_1 + x_2 - 1).$$  \hfill (3.34)

From Theorem 3.2, for each state $(x_1, x_2) \in S$,

$$\alpha V_{\alpha}^*(x_1, x_2) = \min_{(s_{11}, s_{12}, s_{22}) \in A(x_1, x_2)} \left\{ c_1(x_1 - s_{11} - s_{12}) + c_2(x_2 - s_{22}) + \sum_{(x'_1, x'_2) \in S} V_{\alpha}^*(x'_1, x'_2) q[(x'_1, x'_2)| (x_1, x_2), a = (s_{11}, s_{12}, s_{22})]\right\}$$ \hfill (3.35)

By transition rates (3.31),

$$\alpha V_{\alpha}^*(x_1, x_2) = \min_{(s_{11}, s_{12}, s_{22}) \in A(x_1, x_2)} \left\{ c_1 x_1 + c_2 x_2 - c_1 s_{11} - c_1 s_{12} - c_2 s_{22} + \lambda_1 V_{\alpha}^*(x_1 + 1, x_2) + \lambda_2 V_{\alpha}^*(x_1, x_2 + 1) + [\mu_1 s_{11} + \mu_2 s_{12} + \theta_1 (x_1 - s_{11} - s_{12})] V_{\alpha}^*(x_1 - 1, x_2) + [\mu_2 s_{22} + \theta_2 (x_2 - s_{22})] V_{\alpha}^*(x_1, x_2 - 1) - [\lambda_1 + \lambda_2 + \mu_1 s_{11} + \mu_2 (s_{12} + s_{22}) + \theta_1 (x_1 - s_{11} - s_{12}) + \theta_2 (x_2 - s_{22})] V_{\alpha}^*(x_1, x_2) \right\}

= \min_{(s_{11}, s_{12}, s_{22}) \in A(x_1, x_2)} \left\{ C + s_{11} [(\mu_1 - \theta_1) (V_{\alpha}^*(x_1 - 1, x_2) - V_{\alpha}^*(x_1, x_2)) - c_1] + s_{12} [(\mu_2 - \theta_1) (V_{\alpha}^*(x_1 - 1, x_2) - V_{\alpha}^*(x_1, x_2)) - c_1] + s_{22} [(\mu_2 - \theta_2) (V_{\alpha}^*(x_1, x_2 - 1) - V_{\alpha}^*(x_1, x_2)) - c_2] \right\}$$ \hfill (3.36)

where $C$ is the part independent of $s_{11}$, $s_{12}$, and $s_{22}$.

- When $x_1 + x_2 < N_1 + N_2$, because of work-conservation and $x_2 < N_2$,

$$s_{22} = x_2 \quad \text{and} \quad s_{12} = x_1 - s_{11}.$$ \hfill (3.37)
By substituting (3.37) in (3.36),

$$\alpha V_\alpha^*(x_1, x_2) = \min_{(s_{11}, s_{12}, s_{22}) \in A(x_1, x_2)} \{ C' + s_{11}[(\mu_1 - \mu_2)(V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2) - x_1 c_1 - x_2 c_2)] \}$$

(3.38)

in which, \( C' = C + [x_1(\mu_2 - \theta_1) + x_2(\mu_2 - \theta_2)](V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2) - x_1 c_1 - x_2 c_2) \) is also independent of the control variables.

Because \( V_\alpha^*(x_1 + x_2 - 1) - V_\alpha^*(x_1 + x_2) \leq 0 \),

1. if \( \mu_1 < \mu_2 \), one should take the minimum of \( s_{11} \), i.e. the maximum of \( v_1 \).

   Thus, it is optimal to keep idleness in pool 1.

2. if \( \mu_1 > \mu_2 \), one should take the maximum of \( s_{11} \), i.e. the minimum of \( v_1 \).

   Thus, it is optimal to keep idleness in pool 2.

- When \( x_1 + x_2 \geq N_1 + N_2 \), in consequence of work-conservation,

  \[
s_{11} = x_1 \quad \text{and} \quad s_{12} + s_{22} = N_2. \tag{3.39}
\]

By substituting (3.39) in (3.36),

$$\alpha V_\alpha^*(x_1, x_2) = \min_{(s_{11}, s_{12}, s_{22}) \in A(x_1, x_2)} \{ C' + s_{12}[(\theta_1 - \theta_2)(V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1)) - (c_1 - c_2)] \}$$

(3.40)

in which \( C' = C + [x_1(\mu_2 - \theta_1) + N_2(\mu_2 - \theta_2)](V_\alpha^*(x_1 + x_2 - 1) - V_\alpha^*(x_1 + x_2)) - x_1 c_1 - c_2 N_2 \) is independent of the control variables.

Thus, to achieve the minimum of \( \alpha V_\alpha^*(x_1, x_2) \),

1. if \( \theta_1 < \theta_2 \),

   (a) when \( V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1) \leq \frac{c_1 - c_2}{\theta_1 - \theta_2} \), one should take the minimum of \( s_{12} \), i.e. \( s_{12} = N_2 - x_2 \), which means to take the maximum of \( w_1 \). Thus, it is optimal to keep waiting population in class 1;

   (b) when \( V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1) > \frac{c_1 - c_2}{\theta_1 - \theta_2} \), one should take the maximum of \( s_{12} \), i.e. \( s_{12} = (x_1 - N_1) \land N_2 \), which means to take the minimum of \( w_1 \). Thus, it is optimal to keep waiting population in class 2;
2. if $\theta_1 > \theta_2$,

(a) when $V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1) \leq \frac{c_1 - c_2}{\theta_1 - \theta_2}$, one should take the maximum of $s_{12}$; that is, it is optimal to keep waiting population in class 2;

(b) When $V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1) > \frac{c_1 - c_2}{\theta_1 - \theta_2}$, one should take the minimum of $s_{12}$, that is, it is optimal to keep waiting population in class 1.

### 3.4 Optimal control of X model

X model with pool-dependent service rates is another extension of the two-class V model we discussed. Unlike the N model, customers of both classes are able to get service from either of the two pools. As shown in Figure 3.13, pool 1 serves both class-1 and class-2 customers with rate $\mu_1$, while pool 2 servers both classes with rate $\mu_2$.

![Figure 3.13: X model](image)

For this X model, we are still interested in finding the optimal policy that can minimize $E[\int_0^\infty e^{-\alpha t}c(x_1(t), x_2(t), f)dt]$, the expected discount cost of holding customers in queue. This control problem is once again interpreted as a Markov decision problem in this section. We observe the optimal policy obtained by using the policy iteration algorithm, for which the code is presented in Appendix A.3.
3.4.1 Markov decision problem

State space

As suggested by (2.18) in Chapter 2, $N_1^n + N_2^n + O((N_1^n + N_2^n)^{3/2})$ is an asymptotically upper bound of the total number of customers. Hence, we define the state space as

$$S = \{(x_1, x_2)|0 \leq x_i \leq N_1^n + N_2^n + O((N_1^n + N_2^n)^{3/2}), \quad i \in I\}. \quad (3.41)$$

Action space

Considering preemptive, work-conserving and stationary policies, we define the action space for state $(x_1, x_2) \in S$ by

$$A(x_1, x_2) = \{(s_{11}, s_{21}, s_{12}, s_{22})|s_{11} + s_{21} + s_{12} + s_{22} = (x_1 + x_2) \land (N_1 + N_2), 0 \leq s_{ij} \leq x_i, \quad i \in I, \quad j \in J\}, \quad (3.42)$$

where $s_{ij}$ denotes the number of class-$i$ customers served by pool $j$.

Let $w = (w_1, w_2)$ denote the ratios of queued class-1 and class-2 customers. Let $v = (v_1, v_2)$ be the ratios of idle servers in pool 1 and pool 2. Then we have,

$$w_1 = 1 - w_2 = \frac{x_1 - s_{11} - s_{12}}{x_1 + x_2 - N_1 - N_2} \mathbb{1}_{\{x_1 + x_2 > N_1 + N_2\}}, \quad (3.43)$$

where $s_{11} + s_{12} \in [(N_1 + N_2 - x_2) \lor 0, x_1 \land (N_1 + N_2)]$;

$$v_1 = 1 - v_2 = \frac{N_1 - s_{11} - s_{21}}{N_1 + N_2 - x_1 - x_2} \mathbb{1}_{\{x_1 + x_2 < N_1 + N_2\}}, \quad (3.44)$$

where $s_{11} + s_{21} \in [(x_1 + x_2 - N_2) \lor 0, (x_1 + x_2) \land N_1]$.

According to (2.12), $x_1 + x_2$ fluctuates within $[n(\nu_1 + \nu_2) - n^{1/2 + \gamma}, n(\nu_1 + \nu_2) + n^{1/2 + \gamma}]$ in the QED regime. It indicates that $x_i < N_1 + N_2$ for $i \in I$, as well as $N_j < x_1 + x_2$ for $j \in J$. Therefore, $0 \leq w_1 \leq 1, 0 \leq v_1 \leq 1$, and their extreme values can always be achieved.

Transition rates

The transition rate from state $(x_1, x_2)$ to state $(x'_1, x'_2)$ under action $a = (s_{11}, s_{21}, s_{12}, s_{22})$ is
\[ q((x_1', x_2')|(x_1, x_2), a = (s_{11}, s_{21}, s_{12}, s_{22})) = \]

\[
\begin{cases}
\lambda_1 & \text{if } x_1' = x_1 + 1, x_2' = x_2, \\
\lambda_2 & \text{if } x_1' = x_1, x_2' = x_2 + 1, \\
\mu_1 s_{11} + \mu_2 s_{12} + (x_1 - s_{11} - s_{12}) \theta_1 & \text{if } x_1' = x_1 - 1, x_2' = x_2, \\
\mu_1 s_{21} + \mu_2 s_{22} + (x_2 - s_{21} - s_{22}) \theta_2 & \text{if } x_1' = x_1, x_2' = x_2 - 1, \\
\rho & \text{if } x_1' = x_1, x_2' = x_2, \\
0 & \text{otherwise.}
\end{cases}
\]  

(3.45)

where \( \rho = -\lambda_1 - \lambda_2 - \mu_1 (s_{11} + s_{21}) - \mu_2 (s_{12} + s_{22}) - (x_1 - s_{11} - s_{12}) \theta_1 - (x_2 - s_{21} - s_{22}) \theta_2. \)

**Cost function**

For policy \( f = \{(s_{11}(t), s_{21}(t), s_{12}(t), s_{22}(t))\}, \) cost per unit time at time \( t \) is

\[ c(x_1(t), x_2(t), f) = c_1 (x_1(t) - s_{11}(t) - s_{12}(t)) + c_2 (x_2(t) - s_{21}(t) - s_{22}(t)). \]  

(3.46)

### 3.4.2 Numerical analysis

In our MATLAB programs, parameters are chosen as follows.

**Parameters Setting**

- Discount factor \( \alpha = 0.9. \)
- Consider the QED regime, \( \mu_1 = 6, \mu_2 = 8, N_1 = N_2 = 20, \) and \( \lambda_1 = \lambda_2 = 140. \)
- \( \theta_1 = 5, \theta_2 = 1. \)
- \( c_1 = 10, c_2 = 5. \)
- The state space is set as \( S = \{(x_1, x_2) | 0 \leq x_1 \leq 70, 0 \leq x_2 \leq 70\}. \) Because \( N_1 + N_2 + 2(N_1 + N_2)^{\frac{2}{3}} < 70. \)

In the following figures, states are highlighted with the same shape and color as in the previous section. For states marked with green "x", the optimal action is to take the minimum of \( s_{11} + s_{21} \) (or equivalently, the maximum of \( v_1 \)); that is, it is optimal to keep idle servers in pool 1. For states marked with pink "o", the optimal action
is to take the minimum of $s_{11} + s_{12}$ (or equivalently, the maximum of $w_1$); that is, one should keep waiting population in class 2. For states marked with red "∗", the optimal action is to take the maximum of $s_{11} + s_{12}$ (or equivalently, the minimum of $w_1$); that is, one should keep waiting population in class 1. For states marked with blue "+", none of above actions is optimal.

The rectangle windows in the following figures indicate the observation regions. Although, for the pool-dependent X model, there is no unique optimal solution to the static fluid model (2.8), by claim (2.12) we can enlarge the observation region to

$$\{(x_1, x_2)|x_i \in [0, n(v_1 + v_2) + n^{1+\gamma}], \ \forall i \in \mathcal{I}\}. \quad (3.47)$$

where $n = 20$ and $\nu_1 = \nu_2 = 1$, with our parameters.

**Idleness is kept in the slower server pool**

The green triangles in Figure 3.14 suggest it is optimal to keep idle servers in pool 1, of which the service rate is smaller. This is intuitively true because it is more efficient for customers to choose the faster servers when there are available servers in both pools.

**The optimal policy depends on $x_1 + x_2$**

For states $\{(x_1, x_2)|x_1 + x_2 > N_1 + N_2\}$, there are two types of optimal actions within the observation region. One is to keep class-2 customers waiting (pink region); the other is to hold class-1 customers in the queue (red region). The pink and red regions are separated approximately by a straight line $x_1 + x_2 = k$. With our parameters, the bigger $c_1$ is, the bigger $k$ is. For instance, Figure 3.14(b) shows that if $c_1 = 12$, the optimal policy is to keep waiting population in class 2 when $40 < x_1 + x_2 \leq 54$ and in class 1 when $x_1 + x_2 > 54$. Meanwhile, in Figure 3.14(c), the threshold value of $x_1 + x_2$ is . To sum up, the optimal policy depends on $x_1 + x_2$.

**Relation between $\frac{c_1 - c_2}{\theta_1 - \theta_2}$ and $\frac{dV_\alpha^*(x_1, x_2)}{d(x_1 + x_2)}$**

The relation between derivatives $\frac{dV_\alpha^*(x_1, x_2)}{d(x_1 + x_2)} := V_\alpha^*(x_1 + x_2) - V_\alpha^*(x_1 + x_2 - 1)$ and $\frac{c_1 - c_2}{\theta_1 - \theta_2}$ is plotted in Figure 3.15.
Figure 3.14: Optimal policy for X model

The x-axis represents \( x_1 + x_2 \), for which we take \( x_1 + x_2 > N_1 + N_2 \) because that is the case when there exist queued customers. The blue lines describe the derivatives of \( V^*_\alpha(x_1, x_2) \) with respect to \( x_1 + x_2 \); the red lines show the values \( \frac{c_1 - c_2}{\theta_1 - \theta_2} \). One can find Figure 3.15 in accordance with Figure 3.14. For example, in Figure 3.15(b),
the derivatives are less than \( \frac{c_1-c_2}{\theta_1-\theta_2} \) when \( x_1 + x_2 \leq 55 \) and bigger than \( \frac{c_1-c_2}{\theta_1-\theta_2} \) when \( 55 < x_1 + x_2 < 70 \); while in Figure 3.14, 55 is also the threshold value separating the pink and red regions. This coincidence suggests that the optimal policy is to keep class-2 customers waiting when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{c_1-c_2}{\theta_1-\theta_2} \); it is optimal to hold class-1 customers in the queue when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{c_1-c_2}{\theta_1-\theta_2} \). Besides, Figure 3.15 (b), (c) and (d) imply that the optimal expected cost \( V^*_\alpha(x_1, x_2) \) of X model, same as that of N model, is not necessary a convex function of \( x_1 + x_2 \).

### 3.4.3 Proof

In the following, we prove the optimal policy for the control of X model is "bang-bang", which means the control variables \( w \) and \( v \) should take only their extreme values. In the language of queueing systems, it is optimal to keep idle servers in pool
1 and waiting population in either class 1 or class 2. Whether to give priority to class 1 or class 2 is decided by the relationship between \( \frac{\alpha_{1} - \alpha_{2}}{\theta_{1} - \theta_{2}} \) and \( V_{\alpha}^{*}(x_{1} + x_{2})-V_{\alpha}^{*}(x_{1} + x_{2}-1) \).

**Theorem 3.8.** For a pool-dependent \( X \) model, the optimal expected cost \( V_{\alpha}^{*}(x_{1}, x_{2}) \) is a non-decreasing function of the total number of customers \( x_{1} + x_{2} \).

- When \( x_{1} + x_{2} \leq N_{1} + N_{2} \), it is optimal to keep idleness in pool \( j^{*} \), where \( j^{*} = \arg \min \{\mu_{j}, j \in J\} \);
- When \( x_{1} + x_{2} > N_{1} + N_{2} \),
  1. if \( V_{\alpha}^{*}(x_{1} + x_{2}) - V_{\alpha}^{*}(x_{1} + x_{2} - 1) \leq \frac{\alpha_{1} - \alpha_{2}}{\theta_{1} - \theta_{2}} \), it is optimal to keep waiting population in the class \( i^{*} \), where \( i^{*} = \arg \min \{\theta_{i}, i \in I\} \);
  2. if \( V_{\alpha}^{*}(x_{1} + x_{2}) - V_{\alpha}^{*}(x_{1} + x_{2} - 1) > \frac{\alpha_{1} - \alpha_{2}}{\theta_{1} - \theta_{2}} \), it is optimal to keep waiting population in the class \( i^{*} \), where \( i^{*} = \arg \max \{\theta_{i}, i \in I\} \);

**Proof:** First, we show that \( V_{\alpha}^{*}(x_{1}, x_{2}) \) is a non-decreasing function of \( x_{1} + x_{2} \). From (3.43) and (3.44), the control action of our interest can be uniquely determined by \( x_{1}(t) + x_{2}(t) \) when given \( w(t) \) and \( u(t) \); that is, the dynamic of controlling the system depends on the sum \( x_{1}(t) + x_{2}(t) \) rather than \( x_{1}(t) \) and \( x_{2}(t) \). Besides, by (3.43) and (3.46),

\[
c(x_{1}(t), x_{2}(t), f) = [c_{1}w_{1}(t) + c_{2}(1-w_{1}(t))](x_{1}(t)+x_{2}(t)-N_{1}-N_{2})I_{\{x_{1}(t)+x_{2}(t)>N_{1}+N_{2}\}}.
\]

So the cost associated to each transition depends only on the sum \( x_{1}(t) + x_{2}(t) \) as well. Hence, the optimal discount cost \( V_{\alpha}^{*}(x_{1}, x_{2}) = \min_{f \in \mathcal{F}} \mathbb{E}[\int_{0}^{\infty} e^{-\alpha t} c(x_{1}(t), x_{2}(t), f) dt] \) is a non-decreasing function of \( x_{1} + x_{2} \), the sum of initial state. That is to say,

\[
V_{\alpha}^{*}(x_{1} - 1, x_{2}) = V_{\alpha}^{*}(x_{1}, x_{2} - 1) := V_{\alpha}^{*}(x_{1} + x_{2} - 1).
\]

According to Theorem 3.2, for each state \( (x_{1}, x_{2}) \in S \),

\[
\alpha V_{\alpha}^{*}(x_{1}, x_{2}) = \min_{(s_{11},s_{12},s_{21},s_{22}) \in A(x_{1},x_{2})} \{c_{1}(x_{1} - s_{11} - s_{12}) + c_{2}(x_{2} - s_{21} - s_{22})
\]
\[
+ \sum_{(x_{1}',x_{2}') \in S} V_{\alpha}^{*}(x_{1}',x_{2}')q[(x_{1}',x_{2}')|(x_{1},x_{2})], a = (s_{11},s_{12},s_{21},s_{22})\}.
\]

(3.50)
From transition rates (3.45),

\[
\alpha V^*_\alpha(x_1, x_2) = \min_{(s_{11}, s_{21}, s_{12}, s_{22}) \in A(x_1, x_2)} \left\{ \begin{array}{c}
c_1x_1 + c_2x_2 - c_1s_{11} - c_1s_{12} - c_2s_{21} - c_2s_{22} \\
+ \lambda_1 V^*_\alpha(x_1 + 1, x_2) + \lambda_2 V^*_\alpha(x_1, x_2 + 1) + V^*_\alpha(x_1 - 1, x_2)[\mu_1s_{11} + \mu_2s_{12} \\
+ \theta_1(x_1 - s_{11} - s_{12})] + V^*_\alpha(x_1, x_2 - 1)[\mu_1s_{21} + \mu_2s_{22} + \theta_2(x_2 - s_{21} - s_{22})] \\
- V^*_\alpha(x_1, x_2)[\lambda_1 + \lambda_2 + \mu_1(s_{11} + s_{21}) + \mu_2(s_{12} + s_{22}) + \theta_1(x_1 - s_{11} - s_{12}) \\
+ \theta_2(x_2 - s_{21} - s_{22})] \right\}
\]

(3.51)

where \(C\) is the part independent of \(s_{11}, s_{21}, s_{12},\) or \(s_{22}\).

- When \(x_1 + x_2 \leq N_1 + N_2\), because of work-conservation,

\[s_{11} + s_{12} = x_1 \quad \text{and} \quad s_{21} + s_{22} = x_2.\]  

(3.52)

By substituting (3.52) in (3.51),

\[
\alpha V^*_\alpha(x_1, x_2) = \min_{(s_{11}, s_{21}, s_{12}, s_{22}) \in A(x_1, x_2)} \left\{ C' + (s_{11} + s_{21})(\mu_1 - \mu_2)(V^*_\alpha(x_1 + x_2 - 1) - V^*_\alpha(x_1 + x_2)) \right\}
\]

(3.53)

in which, \(C' = C + [x_1(\mu_2 - \theta_1) + x_2(\mu_2 - \theta_2)][V^*_\alpha(x_1 + x_2 - 1) - V^*_\alpha(x_1 + x_2)] - c_1x_2 - c_2x_2\) is independent of the control variables.

Notice that \(V^*_\alpha(x_1 + x_2 - 1) - V^*_\alpha(x_1 + x_2) \leq 0,\)

1. if \(\mu_1 < \mu_2\), one should take the minimum of \(s_{11} + s_{21}\), i.e. \((x_1 + x_2 - N_2)\lor 0\), which indicates to take the maximum of \(v_1\). Thus, it is optimal to keep idle servers in pool 1;

2. if \(\mu_1 > \mu_2\), one should take the maximum of \(s_{11} + s_{21}\), i.e. \((x_1 + x_2) \land N_1\), which indicates to take the minimum of \(v_1\). Thus, it is optimal to keep idle servers in pool 2.
• When \( x_1 + x_2 > N_1 + N_2 \), due to work-conservation,

\[
s_{11} + s_{21} = N_1 \quad \text{and} \quad s_{12} + s_{22} = N_2. \tag{3.54}
\]

Then,

\[
\alpha V^*_\alpha(x_1, x_2) = \min_{(s_{11}, s_{21}, s_{12}, s_{22}) \in A(x_1, x_2)} \left\{ (s_{11} + s_{12}) \left[ (\theta_1 - \theta_2)(V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1)) \right. \right.
\]
\[
- \left. \left. (c_1 - c_2) \right) + C' \right\}
\]

(3.55)
in which \( C' = C + [N_1(\mu_1 - \theta_2) + N_2(\mu_2 - \theta_2)](V^*_\alpha(x_1 + x_2 - 1) - V^*_\alpha(x_1 + x_2)) - c_2(N_1 + N_2) \) is independent of the control variables.

Notice that \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \geq 0 \),

1. if \( \theta_1 < \theta_2 \),
   
   (a) when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{\theta_1 - \theta_2}{\theta_1 - \theta_2} \), one should take the minimum of \( s_{11} + s_{12} \), i.e. \( (N_1 + N_2 - x_2) \lor 0 \), which indicates to take the maximum of \( w_1 \). Thus, it is optimal to keep waiting population in class 1;
   
   (b) when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{\theta_1 - \theta_2}{\theta_1 - \theta_2} \), one should take the maximum of \( s_{11} + s_{12} \); that is, it is optimal to keep waiting population in class 2.

2. if \( \theta_1 > \theta_2 \),
   
   (a) when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) \leq \frac{\theta_1 - \theta_2}{\theta_1 - \theta_2} \), one should take the maximum of \( s_{11} + s_{12} \); that is, it is optimal to keep waiting population in class 2;
   
   (b) when \( V^*_\alpha(x_1 + x_2) - V^*_\alpha(x_1 + x_2 - 1) > \frac{\theta_1 - \theta_2}{\theta_1 - \theta_2} \), one should take the minimum of \( s_{11} + s_{12} \); that is, it is optimal to keep waiting population in class 1.
Chapter 4

Discrete-Event Simulation

4.1 Introduction

Simulation is an effective approach to analyzing complex systems. In queueing theory, simulation is often used to estimate the performance measures of queueing systems. For instance, Garnett and Mandelbaum [8] used simulation to evaluate different control policies and demonstrate their impact on the performance of system.

Queueing system M/M/N can be easily simulated by applying the memoryless property of exponential random variables. However, simulation of the general system G/G/N remains a challenging problem. Inspired by the algorithm of simulating G/G/1 in [22], we provide a simple algorithm for G/G/N system. Furthermore, the simulation approach can be applied to complex queueing networks with general distributed interarrival time, service time and patience time. In this chapter, we first introduce the algorithm for G/G/1 given in [22], then elaborate our algorithm for G/G/N, finally present the algorithms for three extended examples, which are G/G/N with abandonment, V model and N model.

Before going to the details, we introduce two essential components of discrete-event simulation: events and variables. In a queueing system, events usually include customers’ arrival, service completion and, in some cases, abandonment. There are three types of variables often used to keep track of the system: time variable $t$, which is the amount of time elapsed since the start; state variables, which describe the state of the system at time $t$; and counter variables, which count the number of certain events by time $t$. All the variables must be updated when an event takes place. We suggest to enlist the variables for observation.
Note that all below simulation algorithms are introduced with First-Come-First-Served (FCFS) discipline in mind, in which customers are served in the order of their arrivals. When there is more than one class of customers, we assume FCFS discipline within each customer class.

4.2 Simulation of G/G/1 model

In a G/G/1 queueing model (see Figure 4.1), we assume the distributions of interarrival time and service time are $G_A$ and $G_S$, respectively. Customer’s departure event indicates the service completion in this system.

![Figure 4.1: G/G/1 model](image)

The following variables are used to do the simulation:

- $t$: time variable;
- $T$: $T(i)$ is the occurring time of the $i$th event;
- $X$: $X(i)$ is the number of customers in system when the $i$th event happens;
- $t_A$: the next arrival time (after time $t$);
- $t_D$: the next departure time (after time $t$);
- $N_A$: the number of arrivals by time $t$;
- $N_D$: the number of departures by time $t$;

Let $T_D$ denote the ending time of observation. $Y_A$ and $Y_S$ represent, respectively,
the random variables with \( G_A \) and \( G_S \) distributions. The algorithm for \( G/G/1 \) simulation is given as follows.

**Initialization:**

- Set \( t = 0, T(0) = 0, X(0) = 0, N_A = N_D = 0. \)
- Generate the time of first arrival \( t_A = 0 + Y_A. \)
- Set \( t_D = T_D. \)

\( t_D \) is set as \( T_D \) to ensure the first event in this empty system is an arrival.

There are two types of events. If \( t_A \leq t_D \), the upcoming event is an arrival; otherwise, the upcoming event is a departure.

**Loop:**

- Case 1: \( t_A \leq t_D \)
  1. \( t = t_A \) (move along with time \( t_A \)).
  2. \( T(i) = t \) (record the occurring time of the \( i \)th event).
  3. \( X(i) = X(i - 1) + 1. \)
  4. \( N_A = N_A + 1. \)
  5. Generate a \( Y_A \) and reset \( t_A = t + Y_A, \) time of next arrival.
  6. (a) If \( X(i) = 1, \) generate a \( Y_S \) and reset \( t_D = t + Y_S. \)
      Note: \( X(i) = 1 \) means the new customer gets service upon the arrival. Then, his/her service completion time needs to be generated as the next departure time in the system.
      (b) If \( X(i) > 1, \) \( t_D \) remains the same.
      Note: \( X(i) > 1 \) means the new customer joins the queue upon the arrival, so next departure time in the system will not be changed.

- Case 2: \( t_A > t_D \)
  1. \( t = t_D. \)
  2. \( T(i) = t. \)
3. $X(i) = X(i - 1) - 1$.

5. (a) If $X(i) = 0$, reset $t_D = T_D$.

   Note: $X(i) = 0$ means the system is empty. $t_D$ is set as $T_D$ to ensure the next event is an arrival.

   (b) If $X(i) > 0$, generate a $Y_S$ and reset $t_D = t + Y_S$, time of next departure.

A loop is terminated when $\min(t_A, t_D) > T_D$.

Changes of the system’s states can be observed by plotting $(T(i), X(i))$ for all $i$’s. Estimates of performance measures, for example average number of customers and average waiting time, can be calculated with $T$, $X$, $N_A$ and $N_D$.

### 4.3 Simulation of G/G/N model

In a G/G/N queueing model (see Figure 4.2), there can be more than one server in the system. The challenge of simulating G/G/N systems is to follow up the status of the $N$ servers. To solve the problem, a $N \times 1$ vector variable $S$ is created, in which $S(k)$ represents the status of the $k$th server. Let $S(k)$ be the next service completion time if the $k$th server is busy; let $S(k) = T_D$ if the server is idle. Clearly, the next departure time in the system is the earliest service completion time among all the busy servers, which is indeed the minimum element of vector $S$.

![Diagram](image_url)

**Figure 4.2:** G/G/N model
Assume that the service times of the $N$ servers are independent and identically distributed according to $G_S$ distribution. The distribution of interarrival time is $G_A$. Let $Y_A$ and $Y_S$ denote the random variables with $G_A$ and $G_S$ distributions, respectively. The algorithm for $G/G/N$ simulation is shown as below. The code written in MATLAB is given in Appendix B.1

Initialization:

- Set $t = 0$, $T(0) = 0$, $X(0) = 0$, $S = (T_D)_{N \times 1}$, $N_A = N_D = 0$.
- Generate the time of first arrival $t_A = 0 + Y_A$.
- Set $t_D = \min(S) = T_D$.

Loop:

- Case 1: $t_A \leq t_D$
  1. $t = t_A$.
  2. $T(i) = t$.
  3. $X(i) = X(i - 1) + 1$.
  5. Update $t_A$: generate a $Y_A$ and reset $t_A = t + Y_A$.
  6. Update $t_D$:
     (a) If $X(i) \leq N$, generate a $Y_S$, replace one of the $T_D$s in vector $S$ with $t + Y_S$ and reset $t_D = \min(S)$.
        Note: $X(i) \leq N$ means the new customer gets service upon the arrival. Hence one of the idle servers, who corresponds to a $T_D$ in $S$, needs to be assigned to the new customer.
     (b) If $X(i) > N$, $S$ and $t_D$ remain the same.
        Note: $X(i) > N$ means the new customer joins the queue upon the arrival.

- Case 2: $t_A > t_D$
  1. $t = t_D$.
  2. $T(i) = t$. 
3. $X(i) = X(i - 1) - 1$.
5. Update $t_D$:
   (a) If $X(i) \geq N$, generate $Y_S$, replace the element $t_D$ in $S$ with $t + Y_S$ and reset $t_D = \min(S)$.
   Note: $X(i) \geq N$ means there were waiting customers before this departure. Then the server, who contributed to the departure, should serve a waiting customer now.
   (b) If $X(i) < N$, change the element $t_D$ in $S$ to $T_D$ and reset $t_D = \min(S)$.
   Note: $X(i) < N$ means there was no queue. Then the server, who contributed to the departure, should be idle now.

A loop is terminated when $\min(t_A, t_D) > T_D$.

4.4 Three extended examples

The core of the discrete-event simulation is to create variables to track the status of every customer and every server in the system. With these variables, the simulation can be implemented by clarifying the types of events and translating the scheduling and routing policies into the update of variables. This approach of simulation can be applied to queueing models with complex structures and various policies.

4.4.1 Simulation of G/G/N with abandonment

In a G/G/N queueing system with abandonment (see Figure 4.3), customers’ departure events include service completion and abandonment. Consequently, the next departure event is the earlier one between the next service completion and the next abandonment.

To simulate the system, one need to track the patience time of every customer. Hence, a vector variable $R$ is created, in which $R(j)$ represents the patience time of the $j$th arriving customer. Let $R(j) = T_D$ if the $j$th arriving customer is in service or has completed the service.

Denote by $G_R$ the distribution of customers’ patience time. Let $Y_A$, $Y_S$ and $Y_R$ be the random variables with $G_A$, $G_S$ and $G_R$ distributions, respectively. The simulation
Figure 4.3: G/G/N with abandonment

algorithm for G/G/N with abandonment is presented as follows. The code written in MATLAB is provided in Appendix B.2

Initialization:

- Set $t = 0$, $T(0) = 0$, $X(0) = 0$, $S = (T_D)_{N\times1}$, $N_A = N_D = 0$.
- Generate the time of first arrival $t_A = 0 + Y_A$.
- Set $t_D = T_D$.

Loop:

- Case 1: $t_A \leq t_D$ (Arrival)
  1. $t = t_A$.
  2. $T(i) = t$.
  3. $X(i) = X(i - 1) + 1$.
  5. Update $t_A$: generate a $Y_A$ and reset $t_A = t + Y_A$.
  6. Update $t_D$:
     - ✓ if $X(i) \leq N$
(a) set $R(N_A) = T_D$.
Note: $X(i) \leq N$ means there are idle servers, so the newcomer gets service directly.

(b) generate a $Y_S$, replace one of the $T_D$s in vector $S$ with $t + Y_S$.
(c) reset $t_D = \min(S) \land \min(R)$.

✓ if $X(i) > N$
(a) generate a $Y_R$ and set $R(N_A) = t + Y_R$.
(b) $S$ remains the same. Reset $t_D = \min(S) \land \min(R)$.

7. Check whether $t_D \in S$ or $t_D \in R$.

• Case 2: $t_A > t_D$ and $t_D \in S$ (Service completion)

1. $t = t_D$.
2. $T(i) = t$.
3. $X(i) = X(i - 1) - 1$.
5. Update $t_D$:
   ✓ if $X(i) \geq N$
   (a) find the first non-$T_D$ element in $R$ and change it to $T_D$.
   (b) generate a $Y_S$ and replace the element $t_D$ in $S$ with $t + Y_S$.
   (c) reset $t_D = \min(S) \land \min(R)$.
   ✓ if $X(i) < N$
   (a) replace the element $t_D$ in $S$ with $T_D$.
   (b) $R$ remains the same. Reset $t_D = \min(S) \land \min(R)$.
6. Check whether $t_D \in S$ or $t_D \in R$.

• Case 3: $t_A > t_D$ and $t_D \in R$ (Abandonment)

1. $t = t_D$.
2. $T(i) = t$.
3. $X(i) = X(i - 1) - 1$.
5. Update $t_D$:

(a) find the element $t_D$ in $R$ and change it to $T_D$.

(b) $S$ remains the same. Reset $t_D = \min(S) \land \min(R)$.

6. Check whether $t_D \in S$ or $t_D \in R$.

A loop is terminated when $\min(t_A, t_D) > T_D$.

### 4.4.2 Simulation of V model

To simulate a V model (see Figure 4.4), we first need to specify the scheduling and routing policy. Here we consider giving priority to class-1 customers, which means keeping class-2 customers waiting until there is no class-1 customer waiting.

Denote by $G_{A_1}$ and $G_{A_2}$ the distributions of interarrival time of class-1 and class-2 customers. The service time of class 1 and class 2 are distributed according to $G_{S_1}$ and $G_{S_2}$ distributions. Let $Y_{A_1}$, $Y_{A_2}$, $Y_{S_1}$ and $Y_{S_2}$ represent the random variables with $G_{A_1}$, $G_{A_2}$, $G_{S_1}$ and $G_{S_2}$ distributions, respectively.

![Figure 4.4: V model](image)

The following variables are introduced for the simulation:

$t_{A_k}$: The next arrival time of class-$k$ customers after time $t$ ($k = 1, 2$);

$Q_k$: The queue length of class-$k$ customers at time $t$ ($k = 1, 2$);
Then, time of next arrival event in the system is $t_A = \min(t_{A_1}, t_{A_2})$.
The simulation algorithm for V model is shown as below. The code written in MATLAB is given in Appendix B.3

**Initialization:**
- Set $t = 0$, $T(0) = 0$, $X(0) = 0$, $Q_k = 0$ ($k = 1, 2$), $S = (T_D)_{N \times 1}$, $N_A = N_D = 0$.
- Generate $t_{A_k} = 0 + Y_{A_k}$ ($k = 1, 2$), and set $t_A = \min(t_{A_1}, t_{A_2})$.
- Set $t_D = \min(S) = T_D$.

**Loop:**
- Case 1: $t_A \leq t_D$ and $t_A = t_{A_1}$ (Arrival of a class-1 customer)
  1. $t = t_A$.
  2. $T(i) = t$.
  3. $X(i) = X(i - 1) + 1$.
  5. Update $t_A$: generate $t_{A_1} = t + Y_{A_1}$ and reset $t_A = \min(t_{A_1}, t_{A_2})$.
  6. Update $t_D$ and $Q_1$:
     - if $X(i) \leq N$,
       - (a) $Q_1 = 0$;
       - (b) generate a $Y_{S_1}$, replace one of the $T_D$s in vector $S$ with $t + Y_{S_1}$ and reset $t_D = \min(S)$.
     - if $X(i) > N$,
       - (a) $Q_1 = Q_1 + 1$;
       - (b) $S$ and $t_D$ remain the same.
- Case 2: $t_A \leq t_D$ and $t_A = t_{A_2}$ (Arrival of a class-2 customer)
  1. $t = t_A$.
  2. $T(i) = t$.
  3. $X(i) = X(i - 1) + 1$. 
5. Update $t_A$: generate $t_{A_2} = t + Y_{A_2}$ and reset $t_A = \min(t_{A_1}, t_{A_2})$.
6. Update $t_D$ and $Q_2$:
   - if $X(i) \leq N$,
     (a) $Q_2 = 0$;
     (b) generate a $Y_{S_2}$, replace one of the $T_D$s in vector $S$ with $t + Y_{S_2}$ and
         reset $t_D = \min(S)$.
   - if $X(i) > N$
     (a) $Q_2 = Q_2 + 1$;
     (b) $S$ and $t_D$ remain the same.

• Case 3: $t_A > t_D$ (Departure)
  1. $t = t_D$.
  2. $T(i) = t$.
  3. $X(i) = X(i - 1) - 1$.
  5. Update $t_D$ and $Q_k (k = 1, 2)$:
     - if $X(i) < N$:
       (a) $Q_k = 0 (k = 1, 2)$;
       (b) change the element $t_D$ in $S$ to $T_D$ and reset $t_D = \min(S)$.
     - if $X(i) \geq N$:
       ∗ if $Q_1 > 0$,
       (a) $Q_1 = Q_1 - 1$;
       (b) generate a $Y_{S_1}$, replace the element $t_D$ in $S$ with $t + Y_{S_1}$ and
           reset $t_D = \min(S)$.
       ∗ if $Q_1 = 0$:
       (a) $Q_2 = Q_2 - 1$;
       (b) generate a $Y_{S_2}$, replace the element $t_D$ in $S$ with $t + Y_{S_2}$ and
           reset $t_D = \min(S)$.

A loop is terminated when $\min(t_A, t_D) > T_D$. 
4.4.3 Simulation of N model

We simulate a N model in which pool 1 serves customers of class 1 and pool 2 serves customers of both classes (see Figure 4.5). The scheduling and routing policy considered here is keeping idleness in pool 2 and keeping waiting population in class 1. In other words, an arriving class-1 customer would choose to go to pool 1 if there are idle servers in both pools; and when a service in pool 2 ends, the idle server would give priority to class-2 customers if there are waiting customers in both classes.

Let $G_{A_k}$ denote the distribution of interarrival time of class-$k$ customers ($k = 1, 2$). We assume that class-$k$ customers are served by pool $p$, which consists of $N_p$ statistically identical and independent servers, with service time distributed according to $G_{S_{kp}}$ distribution. Denote by $Y_{A_1}, Y_{A_2}, Y_{S_{11}}, Y_{S_{12}}$ and $Y_{S_{22}}$, respectively, the random variables with $G_{A_1}, G_{A_2}, G_{S_{11}}, G_{S_{12}}$ and $G_{S_{22}}$ distributions.

The following variables are introduced to do the simulation, where $p, k \in \{1, 2\}$.

$t$: time variable

$T$: $T(i)$ is the occurring time of the $i$th event

$X_p$: $X_p(i)$ is the number of customers waiting to be or being served by pool $p$ when $i$th event happens

$S_p$: $S_p(j)$ is the service completion time of the $j$th server in pool $p$ (at time $t$). It is a $N_p \times 1$ vector

---

**Figure 4.5: N model**

Let $G_{A_k}$ denote the distribution of interarrival time of class-$k$ customers ($k = 1, 2$). We assume that class-$k$ customers are served by pool $p$, which consists of $N_p$ statistically identical and independent servers, with service time distributed according to $G_{S_{kp}}$ distribution. The following variables are introduced to do the simulation, where $p, k \in \{1, 2\}$.

$t$: time variable

$T$: $T(i)$ is the occurring time of the $i$th event

$X_p$: $X_p(i)$ is the number of customers waiting to be or being served by pool $p$ when $i$th event happens

$S_p$: $S_p(j)$ is the service completion time of the $j$th server in pool $p$ (at time $t$). It is a $N_p \times 1$ vector
\( t_{A_k} \): the next arrival time of class-\( k \) customers (after time \( t \))
\( t_{D_p} \): the next departure time of customers served by pool-\( p \) servers (after time \( t \))
\( N_{A_k} \): the number of arrivals of class-\( k \) customers (by time \( t \))
\( N_{D_p} \): the number of departures from pool \( p \) (by time \( t \))

**Initialization:**

- Set \( t = 0, T(0) = 0, X_p(0) = 0, S_p = (T_D)_{N_p \times 1}, N_{A_k} = N_{D_p} = 0. \) (\( p \in \{1, 2\} \) and \( k \in \{1, 2\} \))
- Generate \( t_{A_k} = 0 + Y_{A_k}. \) (\( k \in \{1, 2\} \))
- Set \( t_{D_p} = \text{min}(S_p) = T_D. \) (\( p \in \{1, 2\} \))

**Loop:**
Take \( t = \text{min}(t_{A_1}, t_{A_2}, t_{D_1}, t_{D_2}) \) and set \( T(i) = t. \)

- **Case 1:** \( t = t_{A_1} \) (Arrival of a class-1 customer)
  1. \( N_{A_1} = N_{A_1} + 1. \)
  2. Update \( t_{A_1} \): generate \( t_{A_1} = t + Y_{A_1}. \)
  3. Update \( X_p \) and \( t_{D_p} \) (\( p = 1, 2 \)):
    - \( \checkmark \) if \( X_1(i - 1) < N_1 \)
      - (a) \( X_1(i) = X_1(i - 1) + 1; X_2(i) = X_2(i - 1). \)
      - (b) generate a \( Y_{S_{11}} \), replace one of the \( T_D \)s in vector \( S_1 \) with \( t + Y_{S_{11}} \) and reset \( t_{D_1} = \text{min}(S_1) \).
    - \( \checkmark \) if \( X_1(i - 1) \geq N_1 \) and \( X_2(i - 1) < N_2 \)
      - (a) \( X_1(i) = X_1(i - 1); X_2(i) = X_2(i - 1) + 1. \)
      - (b) generate a \( Y_{S_{12}} \), replace one of the \( T_D \)s in vector \( S_2 \) with \( t + Y_{S_{12}} \) and reset \( t_{D_2} = \text{min}(S_2) \).
    - \( \checkmark \) if \( X_1(i - 1) \geq N_1 \) and \( X_2(i - 1) \geq N_2 \)
      - (a) \( X_1(i) = X_1(i - 1) + 1; X_2(i) = X_2(i - 1). \)

- **Case 2:** \( t = t_{A_2} \) (Arrival of a class-2 customer)
  1. \( N_{A_2} = N_{A_2} + 1. \)
2. Update \( t_{A_2} \): generate \( t_{A_2} = t + Y_{A_2} \).

3. Update \( X_p \): \( X_1(i) = X_1(i-1) \); \( X_2(i) = X_2(i-1) + 1 \).

4. Update \( t_{D_p} \):
   - ✓ if \( X_2(i-1) < N_2 \), generate a \( Y_{S_{22}} \), replace one of the \( T_{D_S} \) in vector \( S_2 \) with \( t + Y_{S_{22}} \) and reset \( t_{D_2} = \text{min}(S_2) \).
   - ✓ if \( X_2(i-1) \geq N_2 \), \( S_2 \) and \( t_{D_2} \) maintain the same.

- **Case 3:** \( t = t_{D_1} \) (Departure from pool 1)
  1. \( N_{D_1} = N_{D_1} + 1 \).
  2. Update \( X_p \): \( X_1(i) = X_1(i-1) - 1 \); \( X_2(i) = X_2(i) \).
  3. Update \( t_{D_p} \):
     - ✓ if \( X_1(i-1) \leq N_1 \), replace the element \( t_{D_1} \) in \( S_1 \) with \( T_D \) and reset \( t_{D_1} = \text{min}(S_1) \).
     - ✓ if \( X_1(i-1) > N_1 \), generate a \( Y_{S_{11}} \), replace the element \( t_{D_1} \) in \( S_1 \) with \( t + Y_{S_{11}} \) and reset \( t_{D_1} = \text{min}(S_1) \).

- **Case 4:** \( t = t_{D_2} \) (Departure from pool 2)
  1. \( N_{D_2} = N_{D_2} + 1 \).
  2. Update \( X_p \) and \( t_{D_p} \):
     - ✓ if \( X_2(i-1) > N_2 \)
       (a) \( X_1(i) = X_1(i-1) \); \( X_2(i) = X_2(i-1) - 1 \).
       (b) generate a \( Y_{S_{22}} \), replace the element \( t_{D_2} \) in \( S_2 \) with \( t + Y_{S_{22}} \) and reset \( t_{D_2} = \text{min}(S_2) \).
     - ✓ if \( X_2(i-1) \leq N_2 \) and \( X_1(i-1) > N_1 \)
       (a) \( X_1(i) = X_1(i-1) - 1 \); \( X_2(i) = X_2(i-1) \).
       (b) generate a \( Y_{S_{12}} \), replace the element \( t_{D_2} \) in \( S_2 \) with \( t + Y_{S_{12}} \) and reset \( t_{D_2} = \text{min}(S_2) \).
     - ✓ if \( X_2(i-1) \leq N_2 \) and \( X_1(i-1) \leq N_1 \)
       (a) \( X_1(i) = X_1(i-1) \); \( X_2(i) = X_2(i-1) - 1 \).
       (b) replace the element \( t_{D_2} \) in \( S_2 \) with \( T_D \) and reset \( t_{D_2} = \text{min}(S_2) \).

A loop is terminated when \( \text{min}(t_{A_1}, t_{A_2}, t_{D_1}, t_{D_2}) > T_D \).
